Chapter 16

Derandomization, Expanders and Extractors

“God does not play dice with the universe”
Albert Einstein

“Anyone who considers arithmetical methods of producing random digits is, of course, in a state of sin.”
John von Neumann, quoted by Knuth 1981

“How hard could it be to find hay in a haystack?”
Howard Karloff

The concept of a randomized algorithm, though widespread, has both a philosophical and a practical difficulty associated with it.

The philosophical difficulty is best represented by Einstein’s famous quote above. Do random events (such as the unbiased coin flip assumed in our definition of a randomized turing machine) truly exist in the world, or is the world deterministic? The practical difficulty has to do with actually generating random bits, assuming they exist. A randomized algorithm running on a modern computer could need billions of random bits each second. Even if the world contains some randomness — say, the ups and downs of the stock market — it may not have enough randomness to provide billions of uncorrelated random bits every second in the tiny space inside a microprocessor. Current computing environments rely on shortcuts such as taking a small “fairly random looking” bit sequence — e.g., interval between the programmer’s keystrokes measured in microseconds — and applying a deterministic generator to turn them into a longer sequence of “sort of random looking” bits. Some recent devices try to use quantum phenomena. But for all of them it is unclear how random and uncorrelated those bits really are.
Such philosophical and practical difficulties look deterring; the philosophical aspect alone has been on the philosophers’ table for centuries. The results in the current chapter may be viewed as complexity theory's contribution to these questions.

The first contribution concerns the place of randomness in our world. We indicated in Chapter 7 that randomization seems to help us design more efficient algorithms. A surprising conclusion in this chapter is this could be a mirage to some extent. If certain plausible complexity-theoretic conjectures are true (e.g., that certain problems can not be solved by subexponential-sized circuits) then every probabilistic algorithm can be simulated deterministically with only a polynomial slowdown. In other words, randomized algorithms can be derandomized and \( \text{BPP} = \text{P} \). Nisan and Wigderson [?] named this research area \textit{Hardness versus Randomness} since the existence of hard problems is shown to imply derandomization. Section 16.3 shows that the converse is also true to a certain extent: ability to derandomize implies circuit lowerbounds (thus, hardness) for concrete problems. Thus the Hardness ↔ Randomness connection is very real.

Is such a connection of any use at present, given that we have no idea how to prove circuit lowerbounds? Actually, yes. Just as in cryptography, we can use conjectured hard problems in the derandomization instead of provable hard problems, and end up with a win-win situation: if the conjectured hard problem is truly hard then the derandomization will be successful; and if the derandomization fails then it will lead us to an algorithm for the conjectured hard problem.

The second contribution of complexity theory concerns another practical question: how can we run randomized algorithms given only an imperfect source of randomness? We show the existence of \textit{randomness extractors}: efficient algorithms to extract (uncorrelated, unbiased) random bits from any \textit{weakly random} device. Their analysis is unconditional and uses no unproven assumptions. Below, we will give a precise definition of the properties that such a weakly random device needs to have. We do not resolve the question of whether such weakly random devices exist; this is presumably a subject for physics (or philosophy).

A central result in both areas is Nisan and Wigderson’s beautiful construction of a certain \textit{pseudorandom generator}. This generator is tailor-made for derandomization and has somewhat different properties than the \textit{secure} pseudorandom generators we encountered in Chapter 10.

Another result in the chapter is a (unconditional) derandomization of randomized logspace computations, albeit at the cost of some increase in the space requirement.

**Example 16.1 (Polynomial identity testing)**

One example for an algorithm that we would like to derandomize is the algorithm described in Section 7.2.2 for testing if a given polynomial (represented in the form of an arithmetic zero) is the identically zero polynomial. If \( p \) is an \( n \)-variable nonzero polynomial of total degree \( d \) over a large enough finite field \( F \) (\(|F| > 10d\) will do) then most of the vectors \( u \in F^n \) will satisfy \( p(u) \neq 0 \) (see Lemma A.25. Therefore, checking whether \( p \equiv 0 \) can be done by simply choosing a random \( u \in_F F^n \) and applying \( p \) on \( u \). In fact, it is easy to show that there exists a set of \( m^2 \)-vectors \( u^1, \ldots, u^{m^2} \) such that for every such nonzero polynomial \( p \) that can be computed by a size \( m \) arithmetic circuit, there exists an \( i \in [m^2] \) for which \( p(u^i) \neq 0 \).

This suggests a natural approach for a deterministic algorithm: show a deterministic algorithm that for every \( m \in \mathbb{N} \), runs in \( \text{poly}(m) \) time and outputs a set \( u^1, \ldots, u^{m^2} \) of vectors satisfying the above property. This shouldn’t be too difficult— after all the vast majority of the sets of vectors
have this property, so hard can it be to find a single one? (Howard Karloff calls this task “finding a hay in a haystack”). Surprisingly this turns out to be quite hard: without using complexity assumptions, we do not know how to obtain such a set, and in Section 16.3 we will see that in fact such an algorithm will imply some nontrivial circuit lowerbounds.\footnote{Perhaps it should not be so surprising that “finding a hay in a haystack” is so hard. After all, the hardest open problems of complexity— finding explicit functions with high circuit complexity— are of this form, since the vast majority of the functions from $\{0,1\}^n$ to $\{0,1\}$ have exponential circuit complexity.}

## 16.1 Pseudorandom Generators and Derandomization

The main tool in derandomization is a pseudorandom generator. This is a twist on the definition of a \textit{secure} pseudorandom generator we gave in Chapter 10, with the difference that here we consider nonuniform distinguishers —in other words, circuits— and allow the generator to run in exponential time.

### Definition 16.2 (Pseudorandom Generators)

Let $R$ be a distribution over $\{0,1\}^m$, $S \in \mathbb{N}$ and $\epsilon > 0$. We say that $R$ is an \textit{(S, \epsilon)-pseudorandom distribution} if for every circuit $C$ of size at most $S$, \[|\Pr[C(R) = 1] - \Pr[C(U_m) = 1]| < \epsilon\]

where $U_m$ denotes the uniform distribution over $\{0,1\}^m$.

If $S : \mathbb{N} \rightarrow \mathbb{N}$ is a polynomial-time computable monotone function (i.e., $S(m) \geq S(n)$ for $m \geq n$\footnote{We place these easily satisfiable requirements on the function $S$ to avoid weird cases such as generators whose output length is not computable or generators whose output shrinks as the input grows.}) then a function $G : \{0,1\}^* \rightarrow \{0,1\}^*$ is called an \textit{(S(\ell))-pseudorandom generator} (see Figure 16.1) if:

- For every $z \in \{0,1\}^\ell$, $|G(z)| = S(\ell)$ and $G(z)$ can be computed in time $2^{c\ell}$ for some constant $c$. We call the input $z$ the \textit{seed} of the pseudorandom generator.
- For every $\ell \in \mathbb{N}$, $G(U_\ell)$ is an \textit{(S(\ell)^3,1/10)-pseudorandom distribution}.

### Remark 16.3

The choices of the constant 3 and $1/10$ in the definition of an $S(\ell)$-pseudorandom generator are arbitrary and made for convenience.
16.1. PSEUDORANDOM GENERATORS AND DERANDOMIZATION

Figure 16.1: A pseudorandom generator $G$ maps a short uniformly chosen seed $z \in \{0,1\}^\ell$ into a longer output $G(z) \in \{0,1\}^m$ that is indistinguishable from the uniform distribution $U_m$ by any small circuit $C$.

**Lemma 16.4**

Suppose that there exists an $S(\ell)$-pseudorandom generator for some polynomial-time computable monotone $S : \mathbb{N} \rightarrow \mathbb{N}$. Then for every polynomial-time computable function $\ell : \mathbb{N} \rightarrow \mathbb{N}$, $\text{BPTIME}(S(\ell(n))) \subseteq \text{DTIME}(2^{O(\ell(n))})$ for some constant $c$.

**Proof:** A language $L$ is in $\text{BPTIME}(S(\ell(n)))$ if there is an algorithm $A$ that on input $x \in \{0,1\}^n$ runs in time $cS(\ell(n))$ for some constant $c$, and satisfies

$$\Pr_{r \in \{0,1\}^m}[A(x, r) = L(x)] \geq \frac{2}{3}$$

where $m \leq S(\ell(n))$ and we define $L(x) = 1$ if $x \in L$ and $L(x) = 0$ otherwise.

The main idea is that if we replace the truly random string $r$ with the string $G(z)$ produced by picking a random $z \in \{0,1\}^{\ell(n)}$, then an algorithm like $A$ that runs in only $S(\ell)$ time cannot detect this switch most of the time, and so the probability $2/3$ in the previous expression does not drop below $2/3 - 0.1$. Thus to derandomize $A$, we do not need to enumerate over all $r$; it suffices to enumerate over all $z \in \{0,1\}^{\ell(n)}$ and check how many of them make $A$ accept. This derandomized algorithm runs in $\exp(\ell(n))$ time instead of the trivial $2^m$ time.

Now we make this formal. Our deterministic algorithm $B$ will on input $x \in \{0,1\}^n$, go over all $z \in \{0,1\}^{\ell(n)}$, compute $A(x, G(z))$ and output the majority answer. Note this takes $2^{O(\ell(n))}$ time. We claim that for $n$ sufficiently large, the fraction of $z$'s such that $A(x, G(z)) = L(x)$ is at least $\frac{2}{3} - 0.1$. (This suffices to prove that $L \in \text{DTIME}(2^{c\ell(n)})$ as we can “hardwire” into the algorithm the correct answer for finitely many inputs.)

Suppose this is false and there exists an infinite sequence of $x$’s for which $\Pr[A(x, G(z)) = L(x) < 2/3 - 0.1$. Then we would get a distinguisher for the pseudorandom generator —just use the Cook-Levin transformation to construct a circuit that computes the function $z \mapsto A(x, G(z))$, where $x$ is hardwired into the circuit. This circuit has size $O(S(\ell(n))^2)$ which is smaller than $S(\ell(n))^3$ for sufficiently large $n$. ■

**Remark 16.5**

The proof shows why it is OK to allow the pseudorandom generator in Definition 16.2 to run in time exponential in its seed length. The derandomized algorithm enumerates over all possible seeds...
of length \(\ell\), and thus would take exponential time (in \(\ell\)) even if the generator itself were to run in less than exponential time.

Notice, these generators have to fool distinguishers that run for less time than they do. By contrast, the definition of secure pseudorandom generators (Definition 10.11 in Chapter 10) required the generator to run in polynomial time, and yet have the ability to fool distinguishers that have super-polynomial running time. This difference in these definitions stems from the intended usage. In the cryptographic setting the generator is used by honest users and the distinguisher is the adversary attacking the system — and it is reasonable to assume the attacker can invest more computational resources than those needed for normal/honest use of the system. In derandomization, generator is used by the derandomized algorithm, the "distinguisher" is the probabilistic algorithm that is being derandomized, and it is reasonable to allow the derandomized algorithm higher running time than the original probabilistic algorithm.

Of course, allowing the generator to run in exponential time as in this chapter potentially makes it easier to prove their existence compared with secure pseudorandom generators, and this indeed appears to be the case. (Note that if we place no upperbounds on the generator’s efficiency, we could prove the existence of generators unconditionally as shown in Exercise 2, but these do not suffice for derandomization.)

We will construct pseudorandom generators based on complexity assumptions, using quantitatively stronger assumptions to obtain quantitatively stronger pseudorandom generators (i.e., \(S(\ell)\)-pseudorandom generators for larger functions \(S\)). The strongest (though still reasonable) assumption will yield a \(2^{\Omega(\ell)}\)-pseudorandom generator, thus implying that \(\text{BPP} = \text{P}\). These are described in the following easy corollaries of the Lemma that are left as Exercise 1.

\begin{corollary}
1. If there exists a \(2^{\epsilon \ell}\)-pseudorandom generator for some constant \(\epsilon > 0\) then \(\text{BPP} = \text{P}\).

2. If there exists a \(2^{\ell \epsilon}\)-pseudorandom generator for some constant \(\epsilon > 0\) then \(\text{BPP} \subseteq \text{QuasiP} = \text{DTIME}(2^{\text{polylog}(n)})\).

3. If there exists an \(S(\ell)\)-pseudorandom generator for some super-polynomial function \(S\) (i.e., \(S(\ell) = \ell^{\omega(1)}\)) then \(\text{BPP} \subseteq \text{SUBEXP} = \cap_{\epsilon > 0} \text{DTIME}(2^{n^\epsilon})\).
\end{corollary}

### 16.1.1 Hardness and Derandomization

We construct pseudorandom generators under the assumptions that certain explicit functions are hard. In this chapter we use assumptions about average-case hardness, while in the next chapter we will be able to construct pseudorandom generators assuming only worst-case hardness. Both worst-case and average-case hardness refers to the size of the minimum Boolean circuit computing the function:
Let $f : \{0,1\}^* \to \{0,1\}$ be a Boolean function. The **worst-case hardness** of $f$, denoted $H_{wrs}(f)$, is a function from $\mathbb{N}$ to $\mathbb{N}$ that maps every $n \in \mathbb{N}$ to the largest number $S$ such that every Boolean circuit of size at most $S$ fails to compute $f$ on some input in $\{0,1\}^n$.

The **average-case hardness** of $f$, denoted $H_{avg}(f)$, is a function from $\mathbb{N}$ to $\mathbb{N}$ that maps every $n \in \mathbb{N}$, to the largest number $S$ such that $\Pr_{x \in \{0,1\}^n}[C(x) = f(x)] < \frac{1}{2} + \frac{1}{n}$ for every Boolean circuit $C$ on $n$ inputs with size at most $S$.

**Remark 16.8**

This definition of average-case hardness is tailored to the application of derandomization, and in particular only deals with the uniform distribution over the inputs. See Chapter 15 for a more general treatment of average-case complexity. We will also sometimes apply the notions of worst-case and average-case to finite functions from $\{0,1\}^n$ to $\{0,1\}$, where $H_{wrs}(f)$ and $H_{avg}(f)$ are defined in the natural way. (E.g., if $f : \{0,1\}^n \to \{0,1\}$ then $H_{wrs}(f)$ is the largest number $S$ for which every Boolean circuit of size at most $S$ fails to compute $f$ on some input in $\{0,1\}^n$.)

**Example 16.9**

Here are some examples of functions and their conjectured or proven hardness:

1. If $f$ is a random function (i.e., for every $x \in \{0,1\}^*$ we choose $f(x)$ using an independent unbiased coin) then with high probability, both the worst-case and average-case hardness of $f$ are exponential (see Exercise 3). In particular, with probability tending to 1 with $n$, both $H_{wrs}(f)(n)$ and $H_{avg}(f)(n)$ exceed $2^{0.99n}$. We will often use the shorthand $H_{wrs}(f), H_{avg}(f) \geq 2^{0.99n}$ for such expressions.

2. If $f \in \text{BPP}$ then, since $\text{BPP} \subseteq \text{P/poly}$, both $H_{wrs}(f)$ and $H_{avg}(f)$ are bounded by some polynomial.

3. It seems reasonable to believe that 3SAT has exponential worst-case hardness; that is, $H_{wrs}(\text{3SAT}) \geq 2^{\Omega(n)}$. It is even more believable that $\text{NP} \not\subseteq \text{P/poly}$, which implies that $H_{wrs}(\text{3SAT})$ is super-polynomial. The average case complexity of 3SAT is unclear, and in any case dependent upon the way we choose to represent formulas as strings.

4. If we trust the security of current cryptosystems, then we do believe that $\text{NP}$ contains functions that are hard on the average. If $g$ is a one-way permutation that cannot be inverted with polynomial probability by polynomial-sized circuits, then by Theorem 10.14, the function $f$ that maps the pair $x, r \in \{0,1\}^n$ to $g^{-1}(x) \odot r$ has super-polynomial average-case hardness: $H_{avg}(f) \geq n^{o(1)}$. (Where $x \odot r = \sum_{i=1}^n x_i r_i \pmod 2$.) More generally there is a polynomial relationship between the size of the minimal circuit that inverts $g$ (on the average) and the average-case hardness of $f$.,
The main theorem of this section uses hard-on-the-average functions to construct pseudorandom generators:

**Theorem 16.10 (Consequences of NW Generator)**
For every polynomial-time computable monotone $S : \mathbb{N} \rightarrow \mathbb{N}$, if there exists a constant $c$ and function $f \in \text{DTIME}(2^{cn})$ such that $H_{\text{avg}}(f) \geq S(n)$ then there exists a constant $\epsilon > 0$ such that an $S(\epsilon \ell^c)$-pseudorandom generator exists. In particular, the following corollaries hold:

1. If there exists $f \in E = \text{DTIME}(2^{O(n)})$ and $\epsilon > 0$ such that $H_{\text{avg}}(f) \geq 2^{\epsilon n}$ then $\text{BPP} = \text{P}$.
2. If there exists $f \in E = \text{DTIME}(2^{O(n)})$ and $\epsilon > 0$ such that $H_{\text{avg}}(f) \geq 2^{\epsilon n}$ then $\text{BPP} \subseteq \text{QuasiP}$.
3. If there exists $f \in E = \text{DTIME}(2^{O(n)})$ such that $H_{\text{avg}}(f) \geq n^{\omega(1)}$ then $\text{BPP} \subseteq \text{SUBEXP}$.

**Remark 16.11**
We can replace $E$ with $\text{EXP} = \text{DTIME}(2^{\text{poly}(n)})$ in Corollaries 2 and 3 above. Indeed, for every $f \in \text{DTIME}(2^{n^c})$, the function $g$ that on input $x \in \{0,1\}^*$ outputs the first $|x|^{1/c}$ bits of $x$ is in $\text{DTIME}(2^n)$ and satisfies $H_{\text{avg}}(g)(n) \geq H_{\text{avg}}(f)(n^{1/c})$. Therefore, if there exists $f \in \text{EXP}$ with $H_{\text{avg}}(f) \geq 2^{n^c}$ then there exists a constant $\epsilon' > 0$ and a function $g \in E$ with $H_{\text{avg}}(g) \geq 2^{n^\epsilon'}$, and so we can replace $E$ with $\text{EXP}$ in Corollary 2. A similar observation holds for Corollary 3. Note that $\text{EXP}$ contains many classes we believe to have hard problems, such as $\text{NP}, \text{PSPACE}, \text{@P}$ and more, which is why we believe it does contain hard-on-the-average functions. In the next chapter we will give even stronger evidence to this conjecture, by showing it is implied by the assumption that $\text{EXP}$ contains hard-in-the-worst-case functions.

**Remark 16.12**
The original paper of Nisan and Wigderson [?] did not prove Theorem 16.10 as stated above. It was proven in a sequence of works [?]. Nisan and Wigderson only proved that under the same assumptions there exists an $S'(\ell)$-pseudorandom generator, where $S'(\ell) = S\left(\epsilon \sqrt{\ell} \log(S(\epsilon \sqrt{\ell}))\right)^c$ for some $\epsilon > 0$. Note that this is still sufficient to derive all three corollaries above. It is this weaker version we prove in this book.

### 16.2 Proof of Theorem 16.10: Nisan-Wigderson Construction

How can we use a hard function to construct a pseudorandom generator?
16.2. PROOF OF THEOREM 16.10: NISAN-WIGDERSON CONSTRUCTION

16.2.1 Warmup: two toy examples

For starters, we demonstrate this by considering the “toy example” of a pseudorandom generator whose output is only one bit longer than its input. Then we show how to extend by two bits. Of course, neither suffices to prove Theorem 16.10 but they do give insight to the connection between hardness and randomness.

Extending the input by one bit using Yao’s Theorem.

The following Lemma uses a hard function to construct such a “toy” generator:

Lemma 16.13 (One-bit generator)
Suppose that there exist \( f \in \mathbf{E} \) with \( H_{\text{avg}}(f) \geq n^4 \). Then, there exists an \( S(\ell) \)-pseudorandom generator \( G \) for \( S(\ell) = \ell + 1 \).

Proof: The generator \( G \) will be very simple: for every \( z \in \{0, 1\}^\ell \), we set
\[
G(z) = z \circ f(z)
\]
where \( \circ \) denotes concatenation. \( G \) clearly satisfies the output length and efficiency requirements of an \( (\ell+1) \)-pseudorandom generator. To prove that its output is \( 1/10 \)-pseudorandom we use Yao’s Theorem from Chapter 10 showing that pseudorandomness is implied by unpredictability.\(^3\)

Theorem 16.14 (Theorem 10.12, restated)
Let \( Y \) be a distribution over \( \{0, 1\}^m \). Suppose that there exist \( S > 10n, \epsilon > 0 \) such that for every circuit \( C \) of size at most \( 2S \) and \( i \in [m] \),
\[
\Pr_{r \in R_Y} [C(r_1, \ldots, r_{i-1}) = r_i] \leq \frac{1}{2} + \frac{\epsilon}{m}
\]
Then \( Y \) is \((S, \epsilon)\)-pseudorandom.

Using Theorem 16.14 it is enough to show that there does not exist a circuit \( C \) of size \( 2(\ell+1)^3 < \ell^4 \) and a number \( i \in [\ell + 1] \) such that
\[
\Pr_{r = G(U_\ell)} [C(r_1, \ldots, r_{i-1}) = r_i] > \frac{1}{2} + \frac{1}{20(\ell + 1)}.
\] (1)

However, for every \( i \leq \ell \), the \( i^{th} \) bit of \( G(z) \) is completely uniform and independent from the first \( i-1 \) bits, and hence cannot be predicted with probability larger than \( 1/2 \) by a circuit of any size. For \( i = \ell + 1 \), Equation (1) becomes,
\[
\Pr_{z \in R(0,1)^\ell} [C(z) = f(z)] > \frac{1}{2} + \frac{1}{20(\ell + 1)} > \frac{1}{2} + \frac{1}{\ell^4},
\]
which cannot hold under the assumption that \( H_{\text{avg}}(f) \geq n^4 \). \( \blacksquare \)

\(^3\)Although this theorem was stated and proved in Chapter 10 for the case of uniform Turing machines, the proof easily extends to the case of circuits.
Extending the input by two bits using the averaging principle.

We now continue to progress in “baby steps” and consider the next natural toy problem: constructing a pseudorandom generator that extends its input by two bits. This is obtained in the following Lemma:

**Lemma 16.15 (Two-bit generator)**

Suppose that there exists $f \in \mathcal{E}$ with $H_{\text{avg}}(f) \geq n^4$. Then, there exists an $(\ell+2)$-pseudorandom generator $G$.

**Proof:** The construction is again very natural: for every $z \in \{0, 1\}^{\ell}$, we set

$$G(z) = z_1 \cdots z_{\ell/2} \circ f(z_1, \ldots, z_{\ell/2}) \circ z_{\ell/2+1} \cdots z_{\ell} \circ f(z_{\ell/2+1}, \ldots, z_{\ell}).$$

Again, the efficiency and output length requirements are clearly satisfied.

To show $G(U_\ell)$ is $\frac{1}{10}$-pseudorandom, we again use Theorem 16.14, and so need to prove that there does not exist a circuit $C$ of size $2(\ell + 1)^3$ and $i \in [\ell + 2]$ such that

$$\Pr_{r = G(U_\ell)}[C(r_1, \ldots, r_{i-1}) = r_i] > \frac{1}{2} + \frac{1}{20(\ell + 2)}.$$  \hspace{1cm} (2)

Once again, (2) cannot occur for those indices $i$ in which the $i^{th}$ output of $G(z)$ is truly random, and so the only two cases we need to consider are $i = \ell/2 + 1$ and $i = \ell + 2$. Equation (2) cannot hold for $i = \ell/2 + 1$ for the same reason as in Lemma 16.13. For $i = \ell + 2$, Equation (2) becomes:

$$\Pr_{r, r' \in R\{0, 1\}^{\ell/2}}[C(r \circ f(r) \circ r') = f(r')] > \frac{1}{2} + \frac{1}{20(\ell + 2)} \hspace{1cm} (3)$$

This may seem somewhat problematic to analyze since the input to $C$ contains the bit $f(r)$, which $C$ could not compute on its own (as $f$ is a hard function). Couldn’t it be that the input $f(r)$ helps $C$ in predicting the bit $f(r')$? The answer is NO, and the reason is that $r'$ and $r$ are independent. Formally, we use the following principle (see Section A.3.2 in the appendix):

**The Averaging Principle:** If $A$ is some event depending on two independent random variables $X, Y$, then there exists some $x$ in the range of $X$ such that

$$\Pr_Y[A(x, Y) \geq \Pr_{X,Y}[A(X, Y)]]$$

Applying this principle here, if (3) holds then there exists a string $r \in \{0, 1\}^{\ell/2}$ such that

$$\Pr_{r' \in R\{0, 1\}^{\ell/2}}[C(r, f(r), r') = f(r')] > \frac{1}{2} + \frac{1}{20(\ell + 2)}.$$  \hspace{1cm} (Note that this probability is now only over the choice of $r'$.) If this is the case, we can “hardwire” the $\ell/2 + 1$ bits $r \circ f(r)$ to the circuit $C$ and obtain a circuit $D$ of size at most $(\ell + 2)^3 + 2\ell < (\ell/2)^4$ such that

$$\Pr_{r' \in R\{0, 1\}^{\ell/2}}[D(r') = f(r')] > \frac{1}{2} + \frac{1}{20(\ell + 2)},$$

contradicting the hardness of $f$.  \hspace{1cm} ■
16.2. PROOF OF THEOREM ??: NISAN-WIGDERSON CONSTRUCTION

Beyond two bits:

A generator that extends the output by two bits is still useless for our goals. We can generalize the proof Lemma 16.15 to obtain a generator $G$ that extends the output by $k$ bits setting

$$G(z_1, \ldots, z_{\ell}) = z^1 \circ f(z^1) \circ z^2 \circ f(z^2) \cdots z^k \circ f(z^k),$$

where $z^i$ is the $i^{th}$ block of $\ell/k$ bits in $z$. However, no matter how big we set $k$ and no matter how hard the function $f$ is, we cannot get a generator that expands its input by a multiplicative factor larger than two. Note that to prove Theorem 16.10 we need a generator that, depending on the hardness we assume, has output that can be exponentially larger than the input! Clearly, we need a new idea.

16.2.2 The NW Construction

The new idea is still inspired by the construction of (4), but instead of taking $z^1, \ldots, z^k$ to be independently chosen strings (or equivalently, disjoint pieces of the input $z$), we take them to be partly dependent by using combinatorial designs. Doing this will allow us to take $k$ so large that we can drop the actual inputs from the generator’s output and use only $f(z^1) \circ f(z^2) \cdots \circ f(z^k)$.

The proof of correctness is similar to the above toy examples and uses Yao’s technique, except the fixing of the input bits has to be done more carefully because of dependence among the strings.

First, some notation. For a string $z \in \{0,1\}^{\ell}$ and subset $I \subseteq [\ell]$, we define $z \upharpoonright I$ to be the $|I|$-length string that is the projection of $z$ to the coordinates in $I$. For example, $z \upharpoonright [1..i]$ is the first $i$ bits of $z$.

**Definition 16.16 (NW Generator)**

If $I = \{I_1, \ldots, I_m\}$ is a family of subsets of $[\ell]$ with each $|I_j| = l$ and $f: \{0,1\}^n \rightarrow \{0,1\}$ is any function then the $(I, f)$-NW generator (see Figure 16.2) is the function $NW_I: \{0,1\}^{\ell} \rightarrow \{0,1\}^m$ that maps any $z \in \{0,1\}^{\ell}$ to

$$NW_I(z) = f(z \upharpoonright I_1) \circ f(z \upharpoonright I_2) \cdots \circ f(z \upharpoonright I_m)$$

**Figure 16.2:** The NW generator, given a set system $I = \{I_1, \ldots, I_m\}$ of size $n$ subsets of $[\ell]$ and a function $f: \{0,1\}^n \rightarrow \{0,1\}$ maps a string $z \in \{0,1\}^{\ell}$ to the output $f(z \upharpoonright I_1), \ldots, f(z \upharpoonright I_m)$. Note that these sets are not necessarily disjoint (although we will see their intersections need to be small).
16.2. PROOF OF THEOREM ??: NISAN-WIGDERSON CONSTRUCTION

Conditions on the set systems and function.

We will see that in order for the generator to produce pseudorandom outputs, function \( f \) must display some hardness, and the family of subsets must come from an efficiently constructible combinatorial design.

**Definition 16.17 (Combinatorial designs)**

If \( d, n, \ell \in \mathbb{N} \) are numbers with \( \ell > n > d \) then a family \( \mathcal{I} = \{I_1, \ldots, I_m\} \) of subsets of \([\ell]\) is an \((\ell, n, d)\)-design if \( |I_j| = n \) for every \( j \) and \( |I_j \cap I_k| \leq d \) for every \( j \neq k \).

The next lemma yields efficient constructions of these designs and is proved later.

**Lemma 16.18 (Construction of designs)**

There is an algorithm \( A \) such that on input \( \ell, d, n \in \mathbb{N} \) where \( n > d \) and \( \ell > 10n^2/d \), runs for \( 2^{O(\ell)} \) steps and outputs an \((\ell, n, d)\)-design \( \mathcal{I} \) containing \( 2^{d/10} \) subsets of \([\ell]\).

The next lemma shows that if \( f \) is a hard function and \( \mathcal{I} \) is a design with sufficiently good parameters, than \( NW_\mathcal{I}^f(U_\ell) \) is indeed a pseudorandom distribution:

**Lemma 16.19 (Pseudorandomness using the NW generator)**

If \( \mathcal{I} \) is an \((\ell, n, d)\)-design with \( |\mathcal{I}| = 2^{d/10} \) and \( f : \{0,1\}^n \to \{0,1\} \) a function satisfying \( 2^d < \sqrt{H_{eq}(f)}(n) \), then the distribution \( NW_\mathcal{I}^f(U_\ell) \) is a \((H_{eq}(f)(n)/10, 1/10)\)-pseudorandom distribution.

**Proof:** Let \( S \) denote \( H_{eq}(f)(n) \). By Yao’s Theorem, we need to prove that for every \( i \in [2^{d/10}] \) there does not exist an \( S/2 \)-sized circuit \( C \) such that

\[
\Pr_{Z \sim U_{\ell}} \left[ C(R_1, \ldots, R_{i-1}) = R_i \right] \geq \frac{1}{2} + \frac{1}{10 \cdot 2^{d/10}}, \tag{6}
\]

For contradiction’s sake, assume that (6) holds for some circuit \( C \) and some \( i \). Plugging in the definition of \( NW_\mathcal{I}^f \), Equation (6) becomes:

\[
\Pr_{Z \sim U_{\ell}} \left[ C(f(Z_{[I_1]}), \ldots, f(Z_{[I_{i-1}]})) = f(Z_{[I_i]}) \right] \geq \frac{1}{2} + \frac{1}{10 \cdot 2^{d/10}}, \tag{7}
\]

Letting \( Z_1 \) and \( Z_2 \) denote the two independent variables corresponding to the coordinates of \( Z \) in \( I_i \) and \([\ell] \setminus I_i \) respectively, Equation (7) becomes:

\[
\Pr_{Z_{1 \sim U_{\ell_1}}} \left[ C(f_1(Z_1, Z_2), \ldots, f_{i-1}(Z_1, Z_2)) = f(Z_1) \right] \geq \frac{1}{2} + \frac{1}{10 \cdot 2^{d/10}}, \tag{8}
\]

where for every \( j \in [2^{d/10}] \), \( f_j \) applies \( f \) to the coordinates of \( Z_1 \) corresponding to \( I_j \cap I_i \) and the coordinates of \( Z_2 \) corresponding to \( I_j \setminus I_i \). By the averaging principle, if (8) holds then there exists a string \( z_2 \in \{0,1\}^{\ell-n} \) such that

\[
\Pr_{Z_{1 \sim U_{\ell_1}}} \left[ C(f_1(Z_1, z_2), \ldots, f_{i-1}(Z_1, z_2)) = f(Z_1) \right] \geq \frac{1}{2} + \frac{1}{10 \cdot 2^{d/10}}. \tag{9}
\]
16.2. PROOF OF THEOREM 16.10: NISAN-WIGDERSON CONSTRUCTION

We may now appear to be in some trouble, since all of \( f_j(Z_1, z_2) \) for \( j \leq i - 1 \) do depend upon \( Z_1 \), and the fear is that if they together contain enough information about \( Z_1 \) then a circuit could potentially predict \( f_i(Z_1) \) after looking at all of them. To prove that this fear is baseless we use the fact that the circuit \( C \) is small and \( f \) is a very hard function.

Since \( |I_j \cap I_i| \leq d \) for \( j \neq i \), the function \( Z_1 \mapsto f_j(Z_1, z_2) \) depends at most \( d \) coordinates of \( z_1 \) and hence can be computed by a \( d2^d \)-sized circuit. (Recall that \( z_2 \) is fixed.) Thus if if (8) holds then there exists a circuit \( B \) of size \( 2^d/10 \cdot d2^d + S/2 < S \) such that

\[
\Pr_{z_1 \sim U_n} [B(Z_1) = f(Z_1)] \geq \frac{1}{2} + \frac{1}{10 \cdot 2^d/10} > \frac{1}{2} + \frac{1}{S}.
\]

But this contradicts the fact that \( H_{\log}(f)(n) = S \). \( \blacksquare \)

**Remark 16.20 (Black-box proof)**

Lemma 16.19 shows that if \( \text{NW}_f^I(U_\ell) \) is distinguishable from the uniform distribution \( U_{2^d/10} \) by some circuit \( D \), then there exists a circuit \( B \) (of size polynomial in the size of \( D \) and in \( 2^d \) that computes the function \( f \) with probability noticeably larger than \( 1/2 \). The construction of this circuit \( B \) actually uses the circuit \( D \) as a black-box, invoking it on some chosen inputs. This property of the NW generator (and other constructions of pseudorandom generators) turned out to be useful in several settings. In particular, Exercise 5 uses it to show that under plausible complexity assumptions, the complexity class \( \text{AM} \) (containing all languages with a constant round interactive proof, see Chapter 8) is equal to \( \text{NP} \). We will also use this property in the construction of randomness extractors based on pseudorandom generators.

Putting it all together: Proof of Theorem 16.10 from Lemmas 16.18 and 16.19

As noted in Remark 16.12, we do not prove here Theorem 16.10 as stated but only the weaker statement, that given \( f \in \mathbf{E} \) and \( S : \mathbb{N} \to \mathbb{N} \) with \( H_{\log}(f) \geq S \), we can construct an \( S'(\ell) \)-pseudorandom generator, where \( S'(\ell) = S \left( \epsilon \sqrt{\ell} \log(S(\epsilon \sqrt{\ell})) \right) \) for some \( \epsilon > 0 \).

For such a function \( f \), we denote our pseudorandom generator by \( \text{NW}_f^I \). Given input \( z \in \{0, 1\}^\ell \), the generator \( \text{NW}_f^I \) operates as follows:

- Set \( n \) to be the largest number such that \( \ell > 100n^2 / \log S(n) \). Set \( d = \log S(n)/10 \). Since \( S(n) < 2^n \), we can assume that \( \ell \leq 300n^2 / \log S(n) \).

- Run the algorithm of Lemma 16.18 to obtain an \((\ell, n, d)\)-design \( I = \{I_1, \ldots, I_{2d/5}\} \).

- Output the first \( S(n)^{1/40} \) bits of \( \text{NW}_f^I(z) \).

Clearly, \( \text{NW}_f^I(z) \) runs in \( 2^{O(\ell)} \) time. Moreover, since \( 2^d \leq S(n)^{1/10} \), Lemma 16.19 implies that the distribution \( \text{NW}_f^I(U_\ell) \) is \((S(n)/10, 1/10)\)-pseudorandom. Since \( n \geq \sqrt{\ell} \log S(n)/300 \geq \sqrt{\ell} \log S(n)^{1/300} \) (with the last inequality following from the fact that \( S \) is monotone), this concludes the proof of Theorem 16.10. \( \blacksquare \)
Construction of combinatorial designs.

All that is left to complete the proof is to show the construction of combinatorial designs with the required parameters:

**Proof of Lemma 16.18 (Construction of Combinatorial Designs):** On inputs \( \ell, d, n \) with \( \ell > 10n^2/d \), our Algorithm \( A \) will construct an \((\ell, n, d)\)-design \( \mathcal{I} \) with \( 2d/10 \) sets using the simple greedy strategy:

Start with \( \mathcal{I} = \emptyset \) and after constructing \( \mathcal{I} = \{I_1, \ldots, I_m\} \) for \( m < 2d/10 \), search all subsets of \([\ell]\) and add to \( \mathcal{I} \) the first \( n \)-sized set \( I \) satisfying \( |I \cap I_j| \leq d \) for every \( j \in [m] \). We denote this latter condition by (\(*\)).

Clearly, \( A \) runs in \( \text{poly}(m)2^\ell = 2^O(\ell) \) time and so we only need to prove it never gets stuck. In other words, it suffices to show that if \( \ell = 10n^2/d \) and \( \{I_1, \ldots, I_m\} \) is a collection of \( n \)-sized subsets of \([\ell]\) for \( m < 2d/10 \), then there exists an \( n \)-sized subset \( I \subseteq [\ell] \) satisfying (\(*\)). We do so by showing that if we pick \( I \) at random by choosing independently every element \( x \in [\ell] \) to be in \( I \) with probability \( 2n/\ell \) then:

\[
\Pr[|I| \geq n] \geq 0.9 \tag{11}
\]
\[
\Pr[|I \cap I_j| \geq d] \leq 0.5 \cdot 2^{-d/10} \quad (\forall j \in [m]) \tag{12}
\]

Because the expected size of \( I \) is \( 2n \), while the expected size of the intersection \( I \cap I_j \) is \( 2n^2/\ell < d/5 \), both (12) and (11) follow from the Chernoff bound. Yet together these two conditions imply that with probability at least 0.4, the set \( I \) will simultaneously satisfy (\(*\)) and have size at least \( n \). Since we can always remove elements from \( I \) without damaging (\(*\)), this completes the proof. ■

## 16.3 Derandomization Requires Circuit Lowerbounds

We saw in Section 16.2 that if we can prove certain strong circuit lowerbounds, then we can partially (or fully) derandomize \( \text{BPP} \). Now we prove a result in the reverse direction: derandomizing \( \text{BPP} \) requires proving circuit lowerbounds. Depending upon whether you are an optimist or a pessimist, you can view this either as evidence that derandomizing \( \text{BPP} \) is difficult, or, as a reason to double our efforts to derandomize \( \text{BPP} \).

We say that a function is in \( \text{AlgP}/\text{poly} \) if it can be computed by a polynomial size arithmetic circuit whose gates are labeled by \(+, -, \times\) and \(\div\), which are operations over some underlying field or ring. We let \( \text{perm} \) denote the problem of computing the permanent of matrices over the integers. (The proof can be extended to permanent computations over finite fields of characteristic \( > 2 \).) We prove the following result.

**Theorem 16.21 ([?]):**

\( \text{P} = \text{BPP} \Rightarrow \text{NEXP} \not\subset \text{P}/\text{poly} \) or \( \text{perm} \not\in \text{AlgP}/\text{poly} \).
16.3. DERANDOMIZATION REQUIRES CIRCUIT LOWERBOUNDS

**Remark 16.22**
It is possible to replace the “poly” in the conclusion \( \text{perm} \notin \text{AlgP/poly} \) with a subexponential function by appropriately modifying Lemma 16.25. It is open whether the conclusion \( \text{NEXP} \notin \text{P/poly} \) can be similarly strengthened.

In fact, we will prove the following stronger theorem. Recall the *Polynomial Identity Testing* (ZEROP) problem in which the input consists of a polynomial represented by an arithmetic circuit computing it (see Section 7.2.2 and Example 16.1), and we have to decide if it is the identically zero polynomial. This problem is in \( \text{coRP} \subseteq \text{BPP} \) and we will show that if it is in \( \text{P} \) then the conclusions of Theorem 16.21 hold:

**Theorem 16.23 (Derandomization implies lower bounds)**
*If ZEROP \( \in \text{P} \) then either \( \text{NEXP} \notin \text{P/poly} \) or \( \text{perm} \notin \text{AlgP/poly} \).*

The proof relies upon many results described earlier in the book.\(^4\) Recall that \( \text{MA} \) is the class of languages that can be proven by a one round interactive proof between two players Arthur and Merlin (see Definition 8.7). Merlin is an all-powerful prover and Arthur is a polynomial-time verifier that can flip random coins. That is, given an input \( x \), Merlin first sends Arthur a “proof” \( y \). Then Arthur with \( y \) in hand flips some coins and decides whether or not to accept \( x \). For this to be an MA protocol, Merlin must convince Arthur to accept strings in \( L \) with probability one while at the same time Arthur must not be fooled into accepting strings not in \( L \) except with probability smaller than \( 1/2 \). We will use the following result regarding MA:

**Lemma 16.24** ([?], [?])
\( \text{EXP} \subseteq \text{P/poly} \Rightarrow \text{EXP} = \text{MA} \).

**Proof:** Suppose \( \text{EXP} \subseteq \text{P/poly} \). By the Karp-Lipton theorem (Theorem 6.14), in this case \( \text{EXP} \) collapses to the second level \( \Sigma^P_2 \) of the polynomial hierarchy. Hence \( \Sigma^P_2 = \text{PH} = \text{PSPACE} = \text{IP} = \text{EXP} \subseteq \text{P/poly} \). Thus every \( L \in \text{EXP} \) has an interactive proof, and furthermore, since \( \text{EXP} = \text{PSPACE} \), we can just use the interactive proof for TQBF, for which the prover is a PSPACE machine. Hence the prover can be replaced by a polynomial size circuit family \( C_n \). Now we see that the interactive proof can actually be carried out in 2 rounds, with Merlin going first. Given an input \( x \) of length \( n \), Merlin gives Arthur a polynomial size circuit \( C \), which is supposed to be the \( C_n \) for \( L \). Then Arthur runs the interactive proof for \( L \), using \( C \) as the prover. Note that if the input is not in the language, then no prover has a decent chance of convincing the verifier, so this is true also for prover described by \( C \). Thus we have described an MA protocol for \( L \) implying that \( \text{EXP} \subseteq \text{MA} \) and hence that \( \text{EXP} = \text{MA} \). □

Our next ingredient for the proof of Theorem 16.23 is the following lemma:

**Lemma 16.25**
*If ZEROP \( \in \text{P} \), and \( \text{perm} \in \text{AlgP/poly} \). Then \( \text{P}^{\text{perm}} \subseteq \text{NP} \).*

\(^4\)This is a good example of “third generation” complexity results that use a clever combination of both “classical” results from the 60’s and 70’s and newer results from the 1990’s.
Proof: Suppose \( \text{perm} \) has algebraic circuits of size \( n^c \), and that \( \text{ZEROP} \) has a polynomial-time algorithm. Let \( L \) be a language that is decided by an \( n^d \)-time TM \( M \) using queries to a \( \text{perm} \)-oracle. We construct an \( \text{NP} \) machine \( N \) for \( L \).

Suppose \( x \) is an input of size \( n \). Clearly, \( M \)'s computation on \( x \) makes queries to \( \text{perm} \) of size at most \( m = n^d \). So \( N \) will use nondeterminism as follows: it guesses a sequence of \( m \) algebraic circuits \( C_1, C_2, \ldots, C_m \) where \( C_i \) has size \( i^c \). The hope is that \( C_i \) solves \( \text{perm} \) on \( i \times i \) matrices, and \( N \) will verify this in poly\((m)\) time. The verification starts by verifying \( C_1 \), which is trivial. Inductively, having verified the correctness of \( C_1, \ldots, C_{i-1} \), one can verify that \( C_i \) is correct using downward self-reducibility, namely, that for a \( t \times t \) matrix \( A \),

\[
\text{perm}(A) = \sum_{i=1}^{t} a_{1i} \text{perm}(A_{1i}),
\]

where \( A_{1i} \) is the \((t-1) \times (t-1)\) sub-matrix of \( A \) obtained by removing the 1st row and \( i \)th column of \( A \). Thus if circuit \( C_{i-1} \) is known to be correct, then the correctness of \( C_i \) can be checked by substituting \( C_i(A) \) for \( \text{perm}(A) \) and \( C_{i-1}(A_{1i}) \) for \( \text{perm}(A_{1i}) \): this yields an identity involving algebraic circuits with \( t^2 \) inputs which can be verified deterministically in poly\((t)\) time using the algorithm for \( \text{ZEROP} \). Proceeding this way \( N \) verifies the correctness of \( C_1, \ldots, C_m \) and then simulates \( M^{\text{perm}} \) on input \( x \) using these circuits. \( \square \)

The heart of the proof is the following lemma, which is interesting in its own right:

Lemma 16.26 ([?])

\( \text{NEXP} \subseteq \text{P/poly} \Rightarrow \text{NEXP} = \text{EXP} \).

Proof: We prove the contrapositive. Suppose that \( \text{NEXP} \neq \text{EXP} \) and let \( L \in \text{NEXP} \setminus \text{EXP} \). Since \( L \in \text{NEXP} \) there exists a constant \( c > 0 \) and a relation \( R \) such that

\[ x \in L \Leftrightarrow \exists y \in \{0,1\}^{2|c|^c} \text{ s.t. } R(x,y) \text{ holds,} \]

where we can test whether \( R(x,y) \) holds in time \( 2^{2|x|^c} \) for some constant \( c' \).

For every constant \( d > 0 \), let \( M_d \) be the following machine: on input \( x \in \{0,1\}^n \) enumerate over all possible Boolean circuits \( C \) of size \( n^{100d} \) that take \( n^c \) inputs and have a single output. For every such circuit let \( \text{tt}(C) \) be the \( 2^{nc} \)-long string that corresponds to the truth table of the function computed by \( C \). If \( R(x, \text{tt}(C)) \) holds then halt and output 1. If this does not hold for any of the circuits then output 0.

Since \( M_d \) runs in time \( 2^{n^{100d}+n^c} \), under our assumption that \( L \not\subseteq \text{EXP} \), for every \( d \) there exists an infinite sequence of inputs \( X_d = \{x_i\}_{i \in \mathbb{N}} \) on which \( M_d(x_i) \) outputs 0 even though \( x_i \in L \) (note that if \( M_d(x) = 1 \) then \( x \in L \)). This means that for every string \( x \) in the sequence \( X_d \) and every \( y \) such that \( R(x,y) \) holds, the string \( y \) represents the truth table of a function on \( n^c \) bits that cannot be computed by circuits of size \( n^{100d} \), where \( n = |x| \). Using the pseudorandom generator based on worst-case assumptions (Theorem ??), we can use such a string \( y \) to obtain an \( 2^d \)-pseudorandom generator.

Now, if \( \text{NEXP} \subseteq \text{P/poly} \) then as noted above \( \text{NEXP} \subseteq \text{MA} \) and hence every language in \( \text{NEXP} \) has a proof system where Merlin proves that an \( n \)-bit string is in the language by sending
a proof which Arthur then verifies using a probabilistic algorithm of at most \(n^d\) steps. Yet, if \(n\) is the input length of some string in the sequence \(X_d\) and we are given \(x \in X_d\) with \(|x| = n\), then we can replace Arthur by non-deterministic \(\text{poly}(n^d)2^{\mu n}\) time algorithm that does not toss any coins: Arthur will guess a string \(y\) such that \(R(x, y)\) holds and then use \(y\) as a function for a pseudorandom generator to verify Merlin’s proof.

This means that there is a constant \(c > 0\) such that every language in \(\text{NEXP}\) can be decided on infinitely many inputs by a non-deterministic algorithm that runs in \(\text{poly}(2^{n^c})\)-time and uses \(n\) bits of advice (consisting of the string \(x \in X_d\)). Under the assumption that \(\text{NEXP} \subseteq \text{P/poly}\) we can replace the \(\text{poly}(2^{n^c})\) running time with a circuit of size \(n^c\) where \(c\) is a constant depending only on \(c\), and so get that there is a constant \(c'\) such that every language in \(\text{NEXP}\) can be decided on infinitely many inputs by a circuit family of size \(n + n^{c'}\). Yet this can be ruled out using elementary diagonalization. 

**Remark 16.27**
It might seem that Lemma 16.26 should have an easier proof that goes along the proof that \(\text{EXP} \subseteq \text{P/poly} \Rightarrow \text{EXP} = \text{MA}\), but instead of using the interactive proof for \(\text{TQBF}\) uses the multi-prover interactive proof system for \(\text{NEXP}\). However, we do not know how to implement the provers’ strategies for this latter system in \(\text{NEXP}\). (Intuitively, the problem arises from the fact that a \(\text{NEXP}\) statement may have several certificates, and it is not clear how we can ensure all provers use the same one.)

We now have all the ingredients for the proof of Theorem 16.23.

**Proof of Theorem 16.23:** For contradiction’s sake, assume that the following are all true:

\[
\begin{align*}
\text{ZEROP} & \in \text{P} & (13) \\
\text{NEXP} & \subseteq \text{P/poly}, & (14) \\
\text{perm} & \in \text{AlgP/poly}. & (15)
\end{align*}
\]

Statement (14) together with Lemmas 16.24 and 16.26 imply that \(\text{NEXP} = \text{EXP} = \text{MA}\). Now recall that \(\text{MA} \subseteq \text{PH}\), and that by Toda’s Theorem (Theorem 9.11) \(\text{PH} \subseteq \text{P}^\#\text{P}\). Recall also that by Valiant’s Theorem (Theorem 9.8) \(\text{perm}\) is \(\#\text{P}\)-complete. Thus, under our assumptions

\[
\text{NEXP} \subseteq \text{P}^{\text{perm}}. \quad (16)
\]

Since we assume that \(\text{ZEROP} \in \text{P}\), Lemma 16.25 together with statements (15) and (16) implies that \(\text{NEXP} \subseteq \text{NP}\), contradicting the Nondeterministic Time Hierarchy Theorem (Theorem 3.3). Thus the three statements at the beginning of the proof cannot be simultaneously true. 

### 16.4 Explicit construction of expander graphs

Recall that an **expander graph family** is a family of graphs \(\{G_n\}_{n \in I}\) such that for some constants \(\lambda\) and \(d\), for every \(n \in I\), the graph \(G_n\) has \(n\)-vertices, degree \(d\) and its second eigenvalue is at most \(\lambda\). A strongly explicit expander graph family is such a family where there...
is an algorithm that given \( n \) and the index of a vertex \( v \) in \( G_n \), outputs the list of \( v \)'s neighbors in \( \text{poly}(\log(n)) \) time. In this section we show a construction for such a family. Such construction have found several applications in complexity theory and other areas of computer science (one such application is the randomness efficient error reduction procedure we saw in Chapter 7).

The main tools in our construction will be several types of graph products. A graph product is an operation that takes two graphs \( G, G' \) and outputs a graph \( H \). Typically we're interested in the relation between properties of the graphs \( G, G' \) to the properties of the resulting graph \( H \). In this section we will mainly be interested in three parameters: the number of vertices (denoted \( n \)), the degree (denoted \( d \)), and the \( 2^{nd} \) largest eigenvalue of the normalized adjacency matrix (denoted \( \lambda \)), and study how different products affect these parameters. We then use these products to obtain a construction of a strongly explicit expander graph family. In the next section we will use the same products to show a deterministic logspace algorithm for undirected connectivity.

16.4.1 Rotation maps.

In addition to the adjacency matrix representation, we can also represent an \( n \)-vertex degree-\( d \) graph \( G \) as a function \( \hat{G} \) from \( [n] \times [d] \) to \( [n] \) that given a pair \( \langle v, i \rangle \) outputs \( u \) where the \( i^{th} \) neighbor of \( v \) in \( G \). In fact, it will be convenient for us to have \( \hat{G} \) output an additional value \( j \in [d] \) where \( j \) is the index of \( v \) as a neighbor of \( u \). Given this definition of \( \hat{G} \) it is clear that we can invert it by applying it again, and so it is a permutation on \( [n] \times [d] \). We call \( \hat{G} \) the rotation map of \( G \).

For starters, one may think of the case that \( \hat{G}(u, i) = (v, i) \) (i.e., \( v \) is the \( i^{th} \) neighbor of \( u \) if \( u \) is the \( i^{th} \) neighbor of \( v \)). In this case we can think of \( \hat{G} \) as operating only on the vertex. However, we will need the more general notion of a rotation map later on.

We can describe a graph product in the language of graphs, adjacency matrices, or rotation maps. Whenever you see the description of a product in one of this forms (e.g., as a way to map two graphs into one), it is a useful exercise to work out the equivalent descriptions in the other forms (e.g., in terms of adjacency matrices and rotation maps).

16.4.2 The matrix/path product

For every two \( n \) vertex graphs \( G, G' \) with degrees \( d, d' \) and adjacency matrices \( A, A' \), the graph \( G'G \) is the graph described by the adjacency matrix \( A'A \). That is, \( G'G \) has an edge \( (u, v) \) for every length 2-path from \( u \) to \( v \) where the first step in the path is taken on an edge of \( G \) and the second is on an edge of \( G' \). Note that \( G \) has \( n \) vertices and degree \( dd' \). Typically, we are interested in the case \( G = G' \), where it is called graph squaring. More generally, we denote by \( G^k \) the graph \( G \cdot G \cdots G \) \((k \) times\). We already encountered this case before in Lemma 7.27, and similar analysis yields the following lemma (whose proof we leave as exercise):
16.4. EXPLICIT CONSTRUCTION OF EXPANDER GRAPHS

Lemma 16.28 (Matrix product improves expansion)
\[ \lambda(G'G) \leq \lambda(G')\lambda(G') \]

It is also not hard to compute the rotation map of \( G'G \) from the rotation maps of \( G \) and \( G' \). Again, we leave verifying this to the reader.

16.4.3 The tensor product

Let \( G \) and \( G' \) be two graphs with \( n \) (resp \( n' \)) vertices and \( d \) (resp. \( d' \)) degree, and let \( \hat{G} : [n] \times [d] \to [n] \times [d] \) and \( \hat{G}' : [n'] \times [d'] \to [n'] \times [d'] \) denote their respective rotation maps. The tensor product of \( G \) and \( G' \), denoted \( G \otimes G' \), is the graph over \( nn' \) vertices and degree \( dd' \) whose rotation map \( G \otimes G' \) is the permutation over \( ([n] \times [n']) \times ([d] \times [d']) \) defined as follows

\[ G \otimes G'((u, v), (i, j)) = (u', v'), (i', j'), \]

where \( (u', i') = \hat{G}(u, i) \) and \( (v', j') = \hat{G}'(v, j) \). That is, the vertex set of \( G \otimes G' \) is pairs of vertices, one from \( G \) and the other from \( G' \), and taking a step \( (i, j) \) on \( G \otimes G' \) from the vertex \( (u, v) \) is akin to taking two independent steps: move to the pair \( (u', v') \) where \( u' \) is the \( i^{th} \) neighbor of \( u \) in \( G \) and \( v' \) is the \( i^{th} \) neighbor of \( v \) in \( G' \).

In terms of adjacency matrices, the tensor product is also quite easy to describe. If \( A = (a_{i,j}) \) is the \( n \times n \) adjacency matrix of \( G \) and \( A' = (a'_{i',j'}) \) is the \( n' \times n' \) adjacency matrix of \( G' \), then the adjacency matrix of \( G \otimes G' \), denoted as \( A \otimes A' \), will be an \( nn' \times nn' \) matrix that in the \( (i, i') \)\( th \) row and the \( (j, j') \) column has the value \( a_{i,j} \cdot a'_{i',j'} \). That is, \( A \otimes A' \) consists of \( n^2 \) copies of \( A' \), with the \( (i, j) \)\( th \) copy scaled by \( a_{i,j} \):

\[
A \otimes A' = \begin{pmatrix}
a_{1,1}A' & a_{1,2}A' & \cdots & a_{1,n}A' \\
a_{2,1}A' & a_{2,2}A' & \cdots & a_{2,n}A' \\
\vdots & \vdots & \ddots & \vdots \\
a_{n,1}A' & a_{n,2}A' & \cdots & a_{n,n}A'
\end{pmatrix}
\]

The tensor product can also be described in the language of graphs as having a cluster of \( n' \) vertices in \( G \otimes G' \) for every vertex of \( G \). Now if, \( u \) and \( v \) are two neighboring vertices in \( G \), we will put a bipartite version of \( G' \) between the cluster corresponding to \( u \) and the cluster corresponding to \( v \) in \( G \). That is, if \( (i, j) \) is an edge in \( G' \) then there is an edge between the \( i^{th} \) vertex in the cluster corresponding to \( u \) and the \( j^{th} \) vertex in the cluster corresponding to \( v \).
16.4. EXPLICIT CONSTRUCTION OF EXPANDER GRAPHS

Lemma 16.29 (Tensor product preserves expansion)
Let \( \lambda = \lambda(G) \) and \( \lambda' = \lambda(G') \) then \( \lambda(G \otimes G') \leq \max\{\lambda, \lambda'\} \).

One intuition for this bound is the following: taking a \( T \) step random walk on the graph \( G \otimes G' \) is akin to taking two independent random walks on the graphs \( G \) and \( G' \). Hence, if both walks converge to the uniform distribution within \( T \) steps, then so will the walk on \( G \otimes G' \).

Proof: Given some basic facts about tensor products and eigenvalues this is immediate since if \( \lambda_1, \ldots, \lambda_n \) are the eigenvalues of \( A \) (where \( A \) is the adjacency matrix of \( G \)) and \( \lambda'_1, \ldots, \lambda'_m \) are the eigenvalues of \( A' \) (where \( A' \) is the adjacency matrix of \( G' \)), then the eigenvalues of \( A \otimes A' \) are all numbers of the form \( \lambda_i \cdot \lambda'_j \), and hence the largest ones apart from 1 are of the form \( 1 \cdot \lambda'(G') \) or \( \lambda(G) \cdot 1 \) (see also Exercise 14). \( \blacksquare \)

We note that one can show that \( \lambda(G \otimes G') \leq \lambda(G) + \lambda(G') \) without relying on any knowledge of eigenvalues (see Exercise 15). This weaker bound suffices for our applications.

16.4.4 The replacement product

In both the matric and tensor products, the degree of the resulting graph is larger than the degree of the input graphs. The following product will enable us to reduce the degree of one of the graphs. Let \( G, G' \) be two graphs such that \( G \) has \( n \) vertices and degree \( D \), and \( G' \) has \( D' \) vertices and degree \( d \). The balanced replacement product (below we use simply replacement product for short) of \( G \) and \( G' \) is denoted by \( G \odot R G' \) is the \( nn' \)-vertex 2\( d \)-degree graph obtained as follows:

1. For every vertex \( u \) of \( G \), the graph \( G \odot G' \) has a copy of \( G' \) (including both edges and vertices).
2. If \( u, v \) are two neighboring vertices in \( G \) then we place \( d \) parallel edges between the \( i^{th} \) vertex in the copy of \( G' \) corresponding to \( u \) and the \( j^{th} \) vertex in the copy of \( G' \) corresponding to \( v \), where \( i \) is the index of \( v \) as a neighbor of \( u \) and \( j \) is the index of \( u \) as a neighbor of \( v \) in \( G \). (That is, taking the \( i^{th} \) edge out of \( u \) leads to \( v \) and taking the \( j^{th} \) edge out of \( v \) leads to \( u \).)

Note that we essentially already encountered this product in the proof of Claim ?? (see also Figure ??), where we reduced the degree of an arbitrary graph by taking its replacement product with a cycle (although there we did not use parallel edges).\(^5\) The replacement product also has

\(^5\)The addition of parallel edges ensures that a random step from a vertex \( v \) in \( G \odot G' \) will move to a neighbor within the same cluster and a neighbor outside the cluster with the same probability. For this reason, we call this product the balanced replacement product.
a simple description in terms of rotation maps: since \( G \otimes G' \) has \( nD \) vertices and 2\( d \) degree, its rotation map \( G \otimes G' \) is a permutation over \( ([n] \times [D]) \times ([d] \times \{0,1\}) \) and so can be thought of as taking four inputs \( u, v, i, b \) where \( u \in [n] \), \( v \in [D] \), \( i \in [d] \) and \( b \in \{0,1\} \). If \( b = 0 \) then it outputs \( u, G'(v,i), b \) and if \( b = 1 \) then it outputs \( G'(u, v), i, b \). That is, depending on whether \( b \) is equal to 0 or 1, the rotation map either treats \( v \) as a vertex of \( G' \) or as an edge label of \( G \).

In the language of adjacency matrices the replacement product can be easily seen to be described as follows: \( A \otimes A' = \frac{1}{2}(A \otimes I_D) + \frac{1}{2}(I_n \otimes A') \), where \( A, A' \) are the adjacency matrices of the graphs \( G \) and \( G' \) respectively, and \( I_k \) is the \( k \times k \) identity matrix.

If \( D \gg d \) then the replacement product’s degree will be significantly smaller than \( G \)'s degree. The following Lemma shows that this dramatic degree reduction does not cause too much of a deterioration in the graph’s expansion:

**Lemma 16.30 (Expansion of replacement product)**

If \( \lambda(G) \leq 1 - \epsilon \) and \( \lambda(G') \leq 1 - \epsilon' \) then \( \lambda(G \otimes G') \leq 1 - \epsilon' / 4 \).

The intuition behind Lemma 16.30 is the following: Think of the input graph \( G \) as a good expander whose only drawback is that it has a too high degree \( D \). This means that a \( k \) step random walk on \( G' \) requires \( O(k \log D) \) random bits. However, as we saw in Section 7.B.3, sometimes we can use fewer random bits if we use an expander. So a natural idea is to generate the edge labels for the walk by taking a walk using a smaller expander \( G' \) that has \( D \) vertices and degree \( d \ll D \). The definition of \( G \otimes G' \) is motivated by this intuition: a random walk on \( G \otimes G' \) is roughly equivalent to using an expander walk on \( G' \) to generate labels for a walk on \( G \). In particular, each step a walk over \( G \otimes G' \) can be thought of as tossing a coin and then, based on its outcome, either taking a a random step on \( G' \), or using the current vertex of \( G' \) as an edge label to take a step on \( G \).

Another way to gain intuition on the replacement product is to solve Exercise 16, that analyzes the combinatorial (edge) expansion of the resulting graph as a function of the edge expansion of the input graphs.

**Proof of Lemma 16.30:** Let \( A \) (resp. \( A' \)) denote the \( n \times n \) (resp. \( D \times D \)) adjacency matrix of \( G \) (resp. \( G' \)) and let \( \lambda(A) = 1 - \epsilon \) and \( \lambda(A') = 1 - \epsilon' \). Then by Lemma 7.40, \( A = (1-\epsilon)C + J_n \) and \( A' = (1-\epsilon')C' + J_D \), where \( J_k \) is the \( k \times k \) matrix with all entries equal to 1/\( k \).

The adjacency matrix of \( G \otimes G' \) is equal to

\[
\frac{1}{2}(A \otimes I_D) + \frac{1}{2}(I_n \otimes A') = \frac{1-\epsilon}{2} C \otimes I_D + \frac{\epsilon}{2} J_n \otimes I_D + \frac{1-\epsilon'}{2} I_n \otimes C' + \frac{\epsilon'}{2} I_n \otimes J_D ,
\]

where \( I_k \) is the \( k \times k \) identity matrix.

Thus, the adjacency matrix of \( (G \otimes G')^2 \) is equal to

\[
\left( \frac{1-\epsilon}{2} C \otimes I_D + \frac{\epsilon}{2} J_n \otimes I_D + \frac{1-\epsilon'}{2} I_n \otimes C' + \frac{\epsilon'}{2} I_n \otimes J_D \right)^2 = \\
\frac{\epsilon^2}{4}(J_n \otimes I_D)(I_n \otimes J_D) + \frac{\epsilon^2}{4}(I_n \otimes J_D)(J_n \otimes I_D) + (1 - \frac{\epsilon^2'}{2})F ,
\]

where \( F \) is some \( nD \times nD \) matrix of norm at most 1 (obtained by collecting together all the other terms in the expression). But

\[
(J_n \otimes I_D)(I_n \otimes J_D) = (I_n \otimes J_D)(J_n \otimes I_D) = J_n \otimes J_D = J_{nD} .
\]
16.4. EXPLICIT CONSTRUCTION OF EXPANDER GRAPHS

(This can be verified by either direct calculation or by going through the graphical representation or the rotation map representation of the tensor and matrix products.)

Since every vector \( v \in \mathbb{R}^{nD} \) that is orthogonal to \( 1 \) satisfies \( J_{nD}v = 0 \), we get that

\[
(\lambda(G \bar{\otimes} G'))^2 = \lambda((G \bar{\otimes} G')^2) = \lambda \left( (1 - \frac{\epsilon' \epsilon}{2})F + \frac{\epsilon' \epsilon}{2}J_{nD} \right) \leq 1 - \frac{\epsilon' \epsilon}{4},
\]

and hence

\[
\lambda(G \bar{\otimes} G') \leq 1 - \frac{\epsilon' \epsilon}{4}.
\]

\[\square\]

16.4.5 The actual construction.

We now use the three graph products of described above to show a strongly explicit construction of an expander graph family. Recall this is an infinite family \( \{G_k\} \) of graphs (with efficient way to compute neighbors) that has a constant degree and an expansion parameter \( \lambda \). The construction is recursive: we start by a finite size graph \( G_1 \) (which we can find using brute force search), and construct the graph \( G_k \) from the graph \( G_{k-1} \). On a high level the construction is as follows: each of the three product will serve a different purpose in the construction. The Tensor product allows us to take \( G_{k-1} \) and increase its number of vertices, at the expense of increasing the degree and possibly some deterioration in the expansion. The replacement product allows us to dramatically reduce the degree at the expense of additional deterioration in the expansion. Finally, we use the Matrix/Path product to regain the loss in the expansion at the expense of a mild increase in the degree.

**Theorem 16.31 (Explicit construction of expanders)**

There exists a strongly-explicit \( \lambda, d \)-expander family for some constants \( d \) and \( \lambda < 1 \).

**Proof:** Our expander family will be the following family \( \{G_k\}_{k \in \mathbb{N}} \) of graphs:

- Let \( H \) be a \((D = d^{40}, 0.01)\)-graph, which we can find using brute force search. (We choose \( d \) to be a large enough constant that such a graph exists)
- Let \( G_1 \) be a \((D, d^{20}, 1/2)\)-graph, which we can find using brute force search.
- For \( k > 1 \), let \( G_k = ((G_{k-1} \bar{\otimes} G_{k-1}) \bar{\otimes} H)^{20} \).

The proof follows by noting the following points:

1. For every \( k \), \( G_k \) has at least \( 2^{2^k} \) vertices.
   
   Indeed, if \( n_k \) denotes the number of vertices of \( G_k \), then \( n_k = (n_{k-1})^2D \). If \( n_{k-1} \geq 2^{2^k-1} \) then \( n_k \geq \left(2^{2^k-1}\right)^2 = 2^{2^k} \).
2. For every $k$, the degree of $G_k$ is $d^{20}$.

   Indeed, taking a replacement product with $H$ reduces the degree to $d$, which is then increased to $d^{20}$ by taking the $20^{th}$ power of the graph (using the matrix/path product).

3. There is a $2^{O(k)}$-time algorithm that given a label of a vertex $u$ in $G_k$ and an index $i \in [d^{20}]$, outputs the $i^{th}$ neighbor of $u$ in $G_k$. (Note that this is polylogarithmic in the number of vertices.)

   Indeed, such a recursive algorithm can be directly obtained from the definition of $G_k$. To compute $G_k$’s neighborhood function, the algorithm will make 40 recursive calls to $G_{k-1}$’s neighborhood function, resulting in $2^{O(k)}$ running time.

4. For every $k$, $\lambda(G_k) \leq 1/3$.

   Indeed, by Lemmas 16.28, 16.29, and 16.30 if $\lambda(G_{k-1}) \leq 1/3$ then $\lambda(G_{k-1} \otimes G_{k-1}) \leq 2/3$ and hence $\lambda((G_{k-1} \otimes G_{k-1}) \otimes H) \leq 1 - 0.99^{1/2} \approx 1 - 1/13$. Thus, $\lambda(G_k) \leq (1 - 1/13)^{20} \sim e^{-20/13} \leq 1/3$.

Using graph powering we can obtain such a construction for every constant $\lambda \in (0, 1)$, at the expense of a larger degree. There is a variant of the above construction supplying a denser family of graphs that contains an $n$-vertex graph for every $n$ that is a power of $c$, for some constant $c$. Since one can transform an $(n, d, \lambda)$-graph to an $(n', cd', \lambda)$-graph for any $n/c \leq n' \leq n$ by making a single “mega-vertex” out of a set of at most $c$ vertices, the following theorem is also known:

**Theorem 16.32**

There exist constants $d \in \mathbb{N}$, $\lambda < 1$ and a strongly-explicit graph family $\{G_n\}_{n \in \mathbb{N}}$ such that $G_n$ is an $(n, d, \lambda)$-graph for every $n \in \mathbb{N}$.

**Remark 16.33**

As mentioned above, there are known constructions of expanders (typically based on number theory) that are more efficient in terms of computation time and relation between degree and the parameter $\lambda$ than the product-based construction above. However, the proofs for these constructions are more complicated and require deeper mathematical tools. Also, the replacement product (and its close cousin, the zig-zag product) have found applications beyond the constructions of expander graphs. One such application is the deterministic logspace algorithm for undirected connectivity described in the next section. Another application is a construction of combinatorial expanders with greater expansion than what is implied by the parameter $\lambda$. (Note that even for the impossible to achieve value of $\lambda = 0$, Theorem ?? implies combinatorial expansion only $1/2$ while it can be shown that a random graph has combinatorial expansion close to $1$.)

### 16.5 Deterministic logspace algorithm for undirected connectivity.

This section describes a recent result of Reingold, showing that at least the most famous randomized logspace algorithm, the random walk algorithm for $s$-$t$-connectivity in undirected graphs (
Chapter 7) can be completely “derandomized.” Thus the s-t-connectivity problem in undirected graphs is in L.

**Theorem 16.34 (Reingold’s theorem [?])**

\[ \text{UPATH} \in L. \]

Reingold describes a set of poly(n) walks starting from s such that if s is connected to t then one of the walks is guaranteed to hit t. Of course, the existence of such a small set of walks is trivial; this arose in our discussion of universal traversal sequences of Definition ??7. The point is that Reingold’s enumeration of walks can be carried out deterministically in logspace.

In this section, all graphs will be *multigraphs*, of the form \( G = (V, E) \) where \( E \) is a multiset (i.e., some edges may appear multiple times, and each appearance is counted separately). We say the graph is *d-regular* if for each vertex \( i \), the number of edges incident to it is exactly \( d \). We will assume that the input graph for the s-t connectivity problem is d-regular for say \( d = 4 \). This is without loss of generality: if a vertex has degree \( d' < 3 \) we add a self-loop of multiplicity to bring the degree up to \( d \), and if the vertex has degree \( d' \geq 3 \) we can replace it by a cycle of \( d' \) vertices, and each of the \( d' \) edges that were incident to the old vertex then attach to one of the cycle nodes. Of course, the logspace machine does not have space to store the modified graph, but it can pretend that these modifications have taken place, since it can perform them on the fly whenever it accesses the graph. (Formally speaking, the transformation is implicitly computable in logspace; see Claim ??.) In fact, the proof below will perform a series of other local modifications on the graph, each with the property that the logspace algorithm can perform them on the fly.

Recall that checking connectivity in *expander* graphs is easy. Specifically, if every connected component in \( G \) is an expander, then there is a number \( \ell = O(\log n) \) such that if s and t are connected then they are connected with a path of length at most \( \ell \).

**Theorem 16.35**

If an n-vertex graph \( G \) is d-regular graph and \( \lambda(G) < 1/4 \) then the maximum distance between every pair of nodes is at most \( O(d \log n) \).

**Proof:** The exercises ask you to prove that for each subset \( S \) of size at most \( |V|/2 \), the number of edges between \( S \) and \( \overline{S} \) is at least \((1 - \lambda)|S|/2 \geq 3|S|/8\). Thus at least \( 3|S|/8d \) vertices in \( \overline{S} \) must be neighbors of vertices in \( S \). Iterating this argument \( l \) times we conclude the following about the number of vertices whose distance to \( S \) is at most \( l \): it is either more than \( |V|/2 \) (when the abovementioned fact stops applying) or at least \((1 + \frac{3}{8d})^l \). Let \( s, t \) be any two vertices. Using \( S = \{s\} \), we see that at least \( |V|/2 + 1 \) vertices must be within distance \( l = 10d \log n \) of \( s \). The same is true for vertex \( t \). Every two subsets of vertices of size at least \( |V|/2 + 1 \) necessarily intersect, so there must be some vertex within distance \( l \) of both \( s \) and \( t \). Hence the distance from \( s \) to \( t \) is at most \( 2l \). ■

We can enumerate over all \( l \)-step random walks of a d-degree graph in \( O(d \ell) \) space by enumerating over all sequences of indices \( i_1, \ldots, i_\ell \in [d] \). Thus, in a constant-degree graph where all connected components are expanders we can check connectivity in logarithmic space.
The idea behind Reingold’s algorithm is to transform the graph $G$ (in an implicitly computable in logspace way) to a graph $G'$ such that every connected component in $G$ becomes an expander in $G'$, but two vertices that were not connected will stay unconnected.

By adding more self-loops we may assume that the graph is of degree $d^{20}$ for some constant $d$ that is sufficiently large so that there exists a $(d^{20}, d, 0.01)$-graph $H$. (See Fact ?? in the Appendix.) Since the size of $H$ is some constant, we assume the algorithm has access to it (either $H$ could be "hardwired" into the algorithm or the algorithm could perform brute force search to discover it). Consider the following sequence of transformations.

- Let $G_0 = G$.
- For $k \geq 1$, we define $G_k = (G_{k-1} \circledast H)^{20}$.

Here $\circledast$ is the replacement product of the graph, defined in Chapter ??\footnote{We show a recursive algorithm to compute $G_k$ satisfying the equation $s_k = s_{k-1} + O(1)$. In fact, the algorithm will be a pretty straightforward implementation of the definitions of the replacement and matrix products.}. If $G_{k-1}$ is a graph with degree $d^{20}$, then $G_{k-1} \circledast H$ is a graph with degree $d$ and thus $G_k = (G_{k-1} \circledast H)^{20}$ is again a graph with degree $d^{20}$ (and size $(2d^{20}|G_{k-1}|)^{20}$). Note also that if two vertices were connected (resp., disconnected) in $G_{k-1}$, then they are still connected (resp., disconnected) in $G_k$. Thus to solve the UPATH in $G$ it suffices to solve a UPATH problem in any of the $G_k$’s.

Now we show that for $k = O(\log n)$, the graph $G_k$ is an expander, and therefore an easy instance of UPATH. By Lemmas 16.28 and 16.30, for every $\epsilon < 1/20$ and $D$-degree graph $F$, if $\lambda(F) \leq 1 - \epsilon$ then $\lambda(F \circledast H) \leq 1 - \epsilon/5$ and hence $\lambda((F \circledast H)^{20}) \leq 1 - 2\epsilon$. By Lemma 7.28, every connected component of $G$ has expansion parameter at most $1 - 1/(8Dn^3)$, where $n$ denotes the number of $G$’s vertices which is at least as large as the number of vertices in the connect component. It follows that for $k = 10\log D\log N$, in the graph $G_k$ every connected component has expansion parameter at most $\max\{1 - 1/20, 2^k/(8Dn^3)\} = 1 - 1/20$.

To finish, we show how to solve the UPATH problem for $G_k$ in logarithmic space for this value of $k$. The catch is of course that the graph we are given is $G$, not $G_k$. Given $G$, we wish to enumerate length $\ell$ starting from a given vertex in $G_k$ since the graph is an expander. A walk describes, for each step, which of the $d^{20}$ outgoing edges to take from the current vertex. Thus it suffices to show how we can compute in $O(k + \log n)$ space, the $i$th outgoing edge of a given vertex $u$ in $G_k$. This map’s input length is $O(k + \log n)$ and hence we can assume it is placed on a read/write tape, and will compute the rotation map “in-place” changing the input to the output. Let $s_k$ be the additional space (beyond the input) required to compute the rotation map of $G_k$. Note that $s_0 = O(\log n)$.

We show a recursive algorithm to compute $G_k$ satisfying the equation $s_k = s_{k-1} + O(1)$. Now, to compute the rotation map of $(G_{k-1} \circledast H)$ we simply follow the definition of the replacement product. Given this, we can compute the rotation map of $G_{k-1} \circledast H$ in $s_{k-1} + O(1)$ space then we can do so for $G_k$, since we can simply make 20 consecutive calls to this procedure, each time reusing the space.\footnote{One has to be slightly careful while making recursive calls, since we don’t want to lose even the $O(\log \log n)$ bits of writing down $k$ and keeping an index to the location in the input we’re working on. However, this can be done by keeping $k$ in global read/write storage and since storing the identity of the current step among the 50 calls we’re making only requires $O(1)$ space.}
an input of the form $u, v, i, b$ (which we think of as read/write variables), if $b = 0$ then we apply the rotation map of $H$ to $(v, i)$ (can be done in constant space), while if $b = 1$ then we apply the rotation map of $G_{k-1}$ to $(u, v)$ using a recursive call at the cost of $s_{k-1}$ space (note that $u, v$ are conveniently located consecutively at the beginning of the input tape).

16.6 Weak Random Sources and Extractors

Suppose, that despite the philosophical difficulties, we are happy with probabilistic algorithms, and see no need to “derandomize” them, especially at the expense of some unproven assumptions. We still need to tackle the fact that real world sources of randomness and unpredictability rarely, if ever, behave as a sequence of perfectly uncorrelated and unbiased coin tosses. Can we still execute probabilistic algorithms using real-world “weakly random” sources?

16.6.1 Min Entropy

For starters, we need to define what we mean by a weakly random source.

**Definition 16.36**

Let $X$ be a random variable. The min entropy of $X$, denoted by $H_{\infty}(X)$, is the largest real number $k$ such that $\Pr[X = x] \leq 2^{-k}$ for every $x$ in the range of $X$.

If $X$ is a distribution over $\{0, 1\}^n$ with $H_{\infty}(X) \geq k$ then it is called an $(n, k)$-source.

It is not hard to see that if $X$ is a random variable over $\{0, 1\}^n$ then $H_{\infty}(X) \leq n$ with $H_{\infty}(X) = n$ if and only if $X$ is distributed according to the uniform distribution $U_n$. Our goal in this section is to be able to execute probabilistic algorithms given access to a distribution $X$ with $H_{\infty}(X)$ as small as possible. It can be shown that min entropy is a minimal requirement in the sense that in general, to execute a probabilistic algorithm that uses $k$ random bits we need access to a distribution $X$ with $H_{\infty}(X) \geq k$ (see Exercise ??).

**Example 16.37**

Here are some examples for distributions $X$ over $\{0, 1\}^n$ and their min-entropy:

- (Bit fixing and generalized bit fixing sources) If there is subset $S \subseteq [n]$ with $|S| = k$ such that $X$’s projection to the coordinates in $S$ is uniform over $\{0, 1\}^k$, and $X$’s projection to $[n] \setminus S$ is a fixed string (say the all-zeros string) then $H_{\infty}(X) = k$. The same holds if $X$’s projection to $[n] \setminus S$ is a fixed deterministic function of its projection to $S$. For example, if the bits in the odd positions of $X$ are independent and uniform and for every even position $2i$, $X_{2i} = X_{2i-1}$ then $H_{\infty}(X) = \lceil \frac{n}{2} \rceil$. This may model a scenario where we measure some real world data at too high a rate (think of measuring every second a physical event that changes only every minute).

- (Linear subspaces) If $X$ is the uniform distribution over a linear subspace of $GF(2)^n$ of dimension $k$, then $H_{\infty}(X) = k$. (In this case $X$ is actually a generalized bit-fixing source—can you see why?)
• (Biased coins) If \( X \) is composed of \( n \) independent coins, each outputting 1 with probability \( \delta < \frac{1}{2} \) and 0 with probability \( 1 - \delta \), then as \( n \) grows, \( H_\infty(X) \) tends to \( H(\delta)n \) where \( H \) is the Shannon entropy function. That is, \( H(\delta) = \delta \log \frac{1}{\delta} + (1 - \delta) \log \frac{1}{1 - \delta} \).

• (Santha-Vazirani sources) If \( X \) has the property that for every \( i \in [n] \), and every string \( x \in \{0, 1\}^{i-1} \), conditioned on \( X_1 = x_1, \ldots, X_{i-1} = x_{i-1} \) it holds that both \( \Pr[X_i = 0] \) and \( \Pr[X_i = 1] \) are between \( \delta \) and \( 1 - \delta \) then \( H_\infty(X) \geq H(\delta)n \). This can model sources such as stock market fluctuations, where current measurements do have some limited dependence on the previous history.

• (Uniform over subset) If \( X \) is the uniform distribution over a set \( S \subseteq \{0, 1\}^n \) with \( |S| = 2^k \) then \( H_\infty(X) = k \). As we will see, this is a very general case that “essentially captures” all distributions \( X \) with \( H_\infty(X) = k \).

We see that min entropy is a pretty general notion, and distributions with significant min entropy can model many real-world sources of randomness.

16.6.2 Statistical distance and Extractors

Now we try to formalize what it means to extract random — more precisely, almost random — bits from an \((n, k)\) source. To do so we will need the following way of quantifying when two distributions are close.

**Definition 16.38 (statistical distance)**
For two random variables \( X \) and \( Y \) with range \( \{0, 1\}^m \), their statistical distance (also known as variation distance) is defined as \( \delta(X, Y) = \max_{S \subseteq \{0, 1\}^m} \{|\Pr[X \in S] - \Pr[Y \in S]|\} \). We say that \( X, Y \) are \( \epsilon \)-close, denoted \( X \approx \epsilon Y \), if \( \delta(X, Y) \leq \epsilon \).

Statistical distance lies in \([0, 1]\) and satisfies triangle inequality, as suggested by its name. The next lemma gives some other useful properties; the proof is left as an exercise.

**Lemma 16.39**
Let \( X, Y \) be any two distributions taking values in \( \{0, 1\}^n \).

1. \( \delta(X, Y) = \frac{1}{2} \sum_{x \in \{0, 1\}^n} |\Pr[X = x] - \Pr[Y = x]| \).

2. (Restatement of Definition 16.38) \( \delta(X, Y) \geq \epsilon \) if there is a boolean function \( D : \{0, 1\}^m \rightarrow \{0, 1\} \) such that \( |\Pr_{x \in X}[D(x) = 1] - \Pr_{y \in Y}[D(y) = 1]| \geq \epsilon \).

3. If \( f : \{0, 1\}^n \rightarrow \{0, 1\}^s \) is any function, then \( \delta(f(X), f(Y)) \leq \delta(X, Y) \). (Here \( f(X) \) is a distribution on \( \{0, 1\}^s \) obtained by taking a sample of \( X \) and applying \( f \).)

Now we define an extractor. This is a (deterministic) function that transforms an \((n, k)\) source into an almost uniform distribution. It uses a small number of additional truly random bits, denoted by \( t \) in the definition below.
16.6. WEAK RANDOM SOURCES AND EXTRACTORS

**Definition 16.40**
A function $\text{Ext} : \{0,1\}^n \times \{0,1\}^t \rightarrow \{0,1\}^m$ is a $(k, \epsilon)$ extractor if for any $(n, k)$-source $X$, the distribution $\text{Ext}(X, U_t)$ is $\epsilon$-close to $U_m$. (For every $\ell$, $U_\ell$ denotes the uniform distribution over $\{0,1\}^\ell$.)

Equivalently, if $\text{Ext} : \{0,1\}^n \times \{0,1\}^t \rightarrow \{0,1\}^m$ is a $(k, \epsilon)$ extractor, then for every distribution $X$ ranging over $\{0,1\}^n$ of min-entropy $k$, and for every $S \subseteq \{0,1\}^m$, we have

$$\left| \Pr_{a \in X, z \in \{0,1\}^t}[\text{Ext}(a, z) \in S] - \Pr_{r \in \{0,1\}^m}[r \in S] \right| \leq \epsilon$$

We use this fact to show in Section 16.7.2 how to use extractors and $(n, k)$-sources to simulate any probabilistic computation.

**Why an additional input?** Our stated motivation for extractors is to execute probabilistic algorithms without access to perfect unbiased coins. Yet, it seems that an extractor is not sufficient for this task, as we only guarantee that its output is close to uniform if it is given an additional input that is uniformly distributed. First, we note that the requirement of an additional input is necessary: for every function $\text{Ext} : \{0,1\}^n \rightarrow \{0,1\}^m$ and every $k \leq n - 1$ there exists an $(n, k)$-source $X$ such that the first bit of $\text{Ext}(X)$ is constant (i.e., is equal to some value $b \in \{0,1\}$ with probability 1), and so is at least of statistical distance $1/2$ from the uniform distribution (Exercise 7). Second, if the length $t$ of the second input is sufficiently short (e.g., $t = O(\log n)$) then, for the purposes of simulating probabilistic algorithms, we can do without any access to true random coins, by enumerating over all the $2^t$ possible inputs (see Section 16.7.2). Clearly, $t$ has to be somewhat short for the extractor to be non-trivial: for $t \geq m$, we can have a trivial extractor that ignores its first input and outputs the second input. This second input is called the seed of the extractor.

16.6.3 Extractors based upon hash functions

One can use pairwise independent (and even weaker notions of) hash functions to obtain extractors. In this section, $\mathcal{H}$ denotes a family of hash functions $h : \{0,1\}^n \rightarrow \{0,1\}^k$. We say it has collision error $\delta$ if for any $x_1 \neq x_2 \in \{0,1\}^n$, $\Pr_{h \in \mathcal{H}}[h(x_1) = h(x_2)] \leq (1 + \delta)/2^k$. We assume that one can choose a random function $h \in \mathcal{H}$ by picking a string at random from $\{0,1\}^t$. We define the extractor $\text{Ext} : \times \{0,1\}^t \rightarrow \{0,1\}^{k+t}$ as follows:

$$\text{Ext}(x, h) = h(x) \circ h,$$

(17)

where $\circ$ denotes concatenation of strings.

To prove that this is an extractor, we relate the min-entropy to the collision probability of a distribution, which is defined as $\sum_a p_a^2$, where $p_a$ is the probability assigned to string $a$.

**Lemma 16.41**

If a distribution $X$ has min-entropy at least $k$ then its collision probability is at most $1/2^k$.

**Proof:** For every $a$ in $X$’s range, let $p_a$ be the probability that $X = a$. Then, $\sum_a p_a^2 \leq \max_a \{p_a\} (\sum_a p_a) \leq \frac{1}{2^k} \cdot 1 = \frac{1}{2^k}$. □
Lemma 16.42 (Leftover hash lemma)

If \( x \) is chosen from a distribution on \( \{0, 1\}^n \) with min-entropy at least \( k/\delta \) and \( H \) has collision error \( \delta \), then \( h(X) \circ h \) has distance at most \( \sqrt{2\delta} \) to the uniform distribution.

Proof: Left as exercise. (Hint: use the relation between the \( L_2 \) and \( L_1 \) norms)

16.6.4 Extractors based upon random walks on expanders

This section assumes knowledge of random walks on expanders, as described in Chapter ??.

Lemma 16.43

Let \( \epsilon > 0 \). For every \( n \) and \( k \leq n \) there exists a \((k, \epsilon)\)-extractor \( \text{Ext} : \{0, 1\}^n \times \{0, 1\}^t \rightarrow \{0, 1\}^n \) where \( t = O(n - k + \log 1/\epsilon) \).

Proof: Suppose \( X \) is an \((n, k)\)-source and we are given a sample \( a \) from it. Let \( G \) be a \((2^n, d, 1/2)\)-graph for some constant \( d \) (see Definition 7.31 and Theorem 16.32).

Let \( z \) be a truly random seed of length \( t = 10 \log d(n - k + \log 1/\epsilon) = O(n - k + \log 1/\epsilon) \). We interpret \( z \) as a random walk in \( G \) of length \( 10(n - k + \log 1/\epsilon) \) starting from the node whose label is \( a \). (That is, we think of \( z \) as \( 10(n - k + \log 1/\epsilon) \) labels in \([d]\) specifying the steps taken in the walk.) The output \( \text{Ext}(a, z) \) of the extractor is the label of the final node on the walk.

We have \( \|X - 1\|^2_2 = \sum_a \text{Pr}[X = a]^2 \), which is at most \( 2^{-k} \) by Lemma 16.41 since \( X \) is an \((n, k)\)-source. Therefore, after a random walk of length \( t \) the distance to the uniform distribution is (by the upperbound in (??)):

\[
\|M^t X - \frac{1}{2^N} 1\|_1 \leq \lambda_2^t \|X - \frac{1}{2^N} 1\|_2 \sqrt{2N} \leq \lambda_2^t 2^{(N-k)/2}.
\]

When \( t \) is a sufficiently large multiple of \( N - k + \log 1/\epsilon \), this distance is smaller than \( \epsilon \).

16.6.5 An extractor based upon Nisan-Wigderson

This section is still quite rough

Now we describe an elegant construction of extractors due to Trevisan.

Suppose we are given a string \( x \) obtained from an \((N, k)\)-source. How can we extract \( k \) random bits from it, given \( O(\log N) \) truly random bits? Let us check that the trivial idea fails. Using \( 2 \log N \) random bits we can compute a set of \( k \) (where \( k < N - 1 \)) indices that are uniformly distributed and pairwise independent. Maybe we should just output the corresponding bits of \( x \)? Unfortunately, this does not work: the source is allowed to set \( N - k \) bits (deterministically) to 0 so long as the remaining \( k \) bits are completely random. In that case the expected number of random bits in our sample is at most \( k^2/N \), which is less than even 1 if \( k < \sqrt{N} \).

This suggests an important idea: we should first apply some transformation on \( x \) to “smear out” the randomness, so it is not localized in a few bit positions. For this, we will use error-correcting codes. Recall that such codes are used to introduce error-tolerance when transmitting messages over noisy channels. Thus intuitively, the code must have the property that it “smears” every bit of the message all over the transmitted message.
16.6. WEAK RANDOM SOURCES AND EXTRACTORS

Having applied such an encoding to the weakly random string, the construction selects bits from it using a better sampling method than pairwise independent sampling, namely, the Nisan-Wigderson combinatorial design.

Nisan-Wigderson as a sampling method:

In (??) we defined a function \( NW_f, S(z) \) using any function \( f : \{0,1\}^L \to \{0,1\} \) and a combinatorial design \( S \). Note that the definition works for every function, not just hard-to-compute functions. Now we observe that \( NW_f, S(z) \) is actually a way to sample entries from the truth table of \( f \).

Think of \( f \) as a bitstring of length \( 2^L \), namely, its truth table. (Likewise, we can think of any circuit with \( L \)-bit inputs and with 0/1 outputs as computing a string of length \( 2^L \).) Given any \( z \) ("the seed"), \( NW_f, S(z) \) is just a method to use \( z \) to sample a sequence of \( m \) bits from \( f \). This is completely analogous to pairwise independent sampling considered above; see Figure ??.

Figure unavailable in pdf file.

Figure 16.3: Nisan-Wigderson as a sampling method: An \((l, \alpha)\)-design \((S_1, S_2, \ldots, S_m)\) where each \( S_i \subseteq [t], |S_i| = l \) can be viewed as a way to use \( z \in \{0,1\}^t \) to sample \( m \) bits from any string of length \( 2^L \), which is viewed as the truth table of a function \( f : \{0,1\}^L \to \{0,1\} \).

List-decodable codes

The construction will use the following kind of codes.

**Definition 16.44**

If \( \delta > 0 \), a mapping \( \sigma : \{0, 1\}^N \to \{0, 1\}^{\bar{N}} \) is called an error-correcting code that is list-decodable up to error \( 1/2 - \delta \) if for every \( w \in \{0, 1\}^{\bar{N}} \), the number of \( y \in B^N \) such that \( w, \sigma(y) \) disagree in at most \( 1/2 - \delta \) fraction of bits is at most \( 1/\delta^2 \).

The set \( \{ \sigma(x) : x \in \{0, 1\}^N \} \) is called the set of codewords.

The name "list-decodable" owes to the fact that if we transmit \( x \) over a noisy channel after first encoding with \( \sigma \) then even if the channel flips \( 1/2 - \delta \) fraction of bits, there is a small "list" of \( y \) that the received message could be decoded to. (Unique decoding may not be possible, but this will be of no consequence in the construction below.) The exercises ask you to prove that list-decodable codes exist with \( \bar{N} = \text{poly}(N, 1/\delta) \), where \( \sigma \) is computable in polynomial time.

**Trevisan’s extractor:**

Suppose we are given an \((N, k)\)-source. We fix \( \sigma : \{0, 1\}^N \to \{0, 1\}^{\bar{N}} \), a polynomial-time computable code that is list-decodable up to error \( 1/2 - \epsilon/m \). We assume that \( \bar{N} \) is a power of 2 and let \( L = \log_2 \bar{N} \). Now every string \( x \in \{0, 1\}^{\bar{N}} \) may be viewed as a boolean function \( < x > : \{0, 1\}^{L \log \bar{N}} \to \{0, 1\} \) whose truth table is \( x \). Let \( S = (S_1, \ldots, S_m) \) be a \((L, \log m)\) design over \([\bar{t}]\).

The extractor \( \text{Ext} NW : \{0, 1\}^N \times \{0, 1\}^L \to \{0, 1\}^m \) is defined as
That is, $ExtNW$ encodes its first ("weakly random") input $x$ using an error-correcting code, then uses Nisan-Wigderson sampling on the resulting string using the second ("truly random") input $z$ as a seed.

**Lemma 16.45**

For sufficiently large $m$ and for $\epsilon > 2^{-m^2}$, $ExtNW_{\sigma,S}$ is a $(m^3, 2\epsilon)$-extractor.

**Proof:** Let $X$ be an $(N, k)$ source where the min-entropy $k$ is $m^3$. To prove that the distribution $ExtNW(a, z)$ where $a \in X, z \in \{0, 1\}^t$ is close to uniform, it suffices (see our remarks after Definition 16.38) to show for each function $D : \{0, 1\}^m \to \{0, 1\}$ that

$$\left| \Pr_r[D(r) = 1] - \Pr_a \in X, \Pr_z \in \{0, 1\}^t[D(ExtNW(a, z)) = 1] \right| \leq 2\epsilon. \quad (18)$$

For the rest of this proof, we fix an arbitrary $D$ and prove that (18) holds for it.

The role played by this test $D$ is somewhat reminiscent of that played by the distinguisher algorithm in the definition of a pseudorandom generator, except, of course, $D$ is allowed to be arbitrarily inefficient. This is why we will use the black-box version of the Nisan-Wigderson analysis (Corollary ??), which does not care about the complexity of the distinguisher.

Let $B$ be the set of bad $a$’s for this $D$, where string $a \in X$ is bad for $D$ if

$$\left| \Pr[D(r) = 1] - \Pr_{z \in \{0, 1\}^t}[D(ExtNW(a, z)) = 1] \right| > \epsilon.$$

We show that $B$ is small using a counting argument: we exhibit a 1-1 mapping from the set of bad $a$’s to another set $G$, and prove $G$ is small. Actually, here is $G$:

$$G = \{ \text{circuits of size } O(m^2) \} \times \{0, 1\}^{2\log(m/\epsilon)} \times \{0, 1\}^2.$$

The number of circuits of size $O(m^2)$ is $2^{O(m^2 \log m)}$, so $|G| \leq 2^{O(m^2 \log m)} \times 2^{2\log(m/\epsilon)} = 2^{O(m^2 \log m)}$.

Let us exhibit a 1-1 mapping from $B$ to $G$. When $a$ is bad, Corollary ?? implies that there is a circuit $C$ of size $O(m^2)$ such that either the circuit $D(C())$ or its negation –XORed with some fixed bit $b$—agrees with $\sigma(a)$ on a fraction $1/2 + \epsilon/m$ of its entries. (The reason we have to allow either $D(C())$ or its complement is the $|$ sign in the statement of Corollary ??.) Let $w \in \{0, 1\}^N$ be the string computed by this circuit. Then $\sigma(a)$ disagrees with $w$ in at most $1/2 - \epsilon/m$ fraction of bits. By the assumed property of the code $\sigma$, at most $(m/\epsilon)^2$ other codewords have this property. Hence $a$ is completely specified by the following information: (a) circuit $C$; this is specified by $O(m^2 \log m)$ bits (b) whether to use $D(C())$ or its complement to compute $w$, and also the value of the unknown bit $b$; this is specified by 2 bits (c) which of the $(m/\epsilon)^2$ codewords around $w$ to pick as $\sigma(a)$; this is specified by $[2 \log(m/\epsilon)]$ bits assuming the codewords around $w$ are ordered in some canonical way. Thus we have described the mapping from $B$ to $G$.

We conclude that for any fixed $D$, there are at most $2^{O(m^2 \log m)}$ bad strings. The probability that an element $a$ taken from $X$ is bad for $D$ is (by Lemma ??) at most $2^{-m^3} \cdot 2^{O(m^2 \log m)} < \epsilon$ for
16.7. APPLICATIONS OF EXTRACTORS

sufficiently large \( m \). We then have

\[
\left| \Pr_r[D(r) = 1] - \Pr_{a \in X, z \in \{0,1\}^t}[D(ExtNW(a, z)) = 1] \right| \\
\leq \sum_a \Pr[X = a] \left| \Pr[D(r) = 1] - \Pr_{z \in \{0,1\}^t}[D(ExtNW(a, z)) = 1] \right| \\
\leq \Pr[X \in B] + \epsilon \leq 2\epsilon,
\]

where the last line used the fact that if \( a \not\in B \), then by definition of \( B \),
\[
\left| \Pr[D(r) = 1] - \Pr_{z \in \{0,1\}^t}[D(ExtNW(a, z)) = 1] \right| \leq \epsilon. \quad \blacksquare
\]

The following theorem is an immediate consequence of the above lemma.

**Theorem 16.46**

Fix a constant \( \epsilon \); for every \( N \) and \( k = N^{\Omega(1)} \) there is a polynomial-time computable \((k, \epsilon)\)-extractor \( Ext : \{0,1\}^N \times \{0,1\}^t \rightarrow \{0,1\}^m \) where \( m = k^{1/3} \) and \( t = O(\log N) \).

16.7 Applications of Extractors

Extractors are deterministic objects with strong pseudorandom properties. We describe a few important uses for them; many more will undoubtedly be found in future.

16.7.1 Graph constructions

An extractor is essentially a graph-theoretic object; see Figure ???. (In fact, extractors have been used to construct expander graphs.) Think of a \((k, \epsilon)\) extractor \( Ext : \{0,1\}^N \times \{0,1\}^t \rightarrow \{0,1\}^m \) as a bipartite graph whose left side contains one node for each string in \( \{0,1\}^N \) and the right side contains a node for each string in \( \{0,1\}^m \). Each node \( a \) on the left is incident to \( 2^t \) edges, labelled with strings in \( \{0,1\}^t \), with the right endpoint of the edge labeled with \( z \) being \( Ext(a, z) \).

An \((N,k)\)-source corresponds to any distribution on the left side with min-entropy at least \( k \). The extractor’s definition implies that picking a node according to this distribution and a random outgoing edge gives a node on the right that is essentially uniformly distributed.

Figure unavailable in pdf file.

Figure 16.4: An extractor \( Ext : \{0,1\}^N \times \{0,1\}^t \rightarrow \{0,1\}^m \) defines a bipartite graph where every node on the left has degree \( 2^t \).

This implies in particular that for every set \( X \) on the left side of size exactly \( 2^k \) — notice, this is a special case of an \((N,k)\)-source — its neighbor set \( \Gamma(X) \) on the right satisfies \( |\Gamma(X)| \geq (1 - \epsilon)2^m \).

One can in fact show a converse, that high expansion implies that the graph is an extractor; see Chapter notes.
16.7.2 Running randomized algorithms using weak random sources

We now describe how to use extractors to simulate probabilistic algorithms using weak random sources. Suppose that \( A(\cdot, \cdot) \) is a probabilistic algorithm that on an input of length \( n \) uses \( m = m(n) \) random bits, and suppose that for every \( x \) we have \( \Pr_r[A(x, r) = \text{right answer}] \geq 3/4 \). If \( A \)'s answers are 0/1, then such algorithms can be viewed as defining a \( \text{BPP} \) language, but here we allow a more general scenario. Suppose \( \text{Ext} : \{0,1\}^N \times \{0,1\}^t \rightarrow \{0,1\}^m \) is a \((k,1/4)\)-extractor.

Consider the following algorithm \( A' \): on input \( x \in \{0,1\}^n \) and given a string \( a \in \{0,1\}^N \) from the weakly random source, the algorithm enumerates all choices for the seed \( z \) and computes \( A(x, \text{Ext}(a, z)) \). Let

\[
A'(x, a) = \text{majority value of } \{ A(x, \text{Ext}(a, z)) : z \in \{0,1\}^t \}
\]

The running time of \( A' \) is approximately \( 2^k \) times that of \( A \). We show that if \( a \) comes from an \((n,k+2)\) source, then \( A' \) outputs the correct answer with probability at least 3/4.

Fix the input \( x \). Let \( R = \{ r \in \{0,1\}^m : A(x, r) = \text{right answer} \} \), and thus \( |R| \geq \frac{3}{4} 2^m \). Let \( B \) be the set of strings \( a \in \{0,1\}^N \) for which the majority answer computed by algorithm \( A' \) is incorrect, namely,

\[
B = \{ a : \Pr_{z \in \{0,1\}^t}[A(x, \text{Ext}(a, z)) = \text{right answer}] < 1/2 \}
\]

Claim: \( |B| \leq 2^k \).

Let random variable \( Y \) correspond to picking an element uniformly at random from \( B \). Thus \( Y \) has min-entropy \( \log B \), and may be viewed as a \((N, \log B)\)-source. By definition of \( B \),

\[
\Pr_{a \in Y, z \in \{0,1\}^t}[\text{Ext}(a, z) \in R] < 1/2.
\]

But \( |R| = \frac{3}{4} 2^m \), so we have

\[
\left| \Pr_{a \in Y, z \in \{0,1\}^t}[\text{Ext}(a, z) \in R] - \Pr_{r \in \{0,1\}^m}[r \in R] \right| > 1/4,
\]

which implies that the statistical distance between the uniform distribution and \( \text{Ext}(Y, z) \) is at least 1/4. Since \( \text{Ext} \) is a \((k,1/4)\)-extractor, \( Y \) must have min-entropy less than \( k \). Hence \( |B| \leq 2^k \) and the Claim is proved.

The correctness of the simulation now follows since

\[
\Pr_{a \in X}[A'(x, a) = \text{right answer}] = 1 - \Pr_{a \in X}[a \in B] \\
\geq 1 - 2^{-(k+2)} \cdot |B| \geq 3/4, \quad \text{(by Lemma ??)}.
\]

Thus we have shown the following.

**Theorem 16.47**

Suppose \( A \) is a probabilistic algorithm running in time \( T_A(n) \) and using \( m(n) \) random bits on inputs of length \( n \). Suppose we have for every \( m(n) \) a construction of a \((k(n), 1/4)\)-extractor \( \text{Ext}_n : \{0,1\}^N \times \{0,1\}^{t(n)} \rightarrow \{0,1\}^{m(n)} \) running in \( T_E(n) \) time. Then \( A \) can be simulated in time \( 2^t(T_A + T_E) \) using one sample from a \((N, k+2)\) source.
16.7. APPLICATIONS OF EXTRACTORS

16.7.3 Recycling random bits

We addressed the issue of recycling random bits in Section ???. An extractor can also be used to recycle random bits. (Thus it should not be surprising that random walks on expanders, which were used to recycle random bits in Section ???, were also used to construct extractors above.)

Suppose $A$ be a randomized algorithm that uses $m$ random bits. Let $\text{Ext} : \{0, 1\}^N \times \{0, 1\}^t \rightarrow \{0, 1\}^m$ be any $(k, \epsilon)$-extractor. Consider the following algorithm. Randomly pick a string $a \in \{0, 1\}^N$, and obtain $2^t$ strings in $\{0, 1\}^m$ obtained by computing $\text{Ext}(a, z)$ for all $z \in \{0, 1\}^t$. Run $A$ for all these random strings. Note that this manages to run $A$ as many as $2^t$ times while using only $N$ random bits. (For known extractor constructions, $N \ll 2^t m$, so this is a big saving.)

Now we analyse how well the error goes down. Suppose $D \subseteq \{0, 1\}^m$ be the subset of strings for which $A$ gives the correct answer. Let $p = |D|/2^m$; for a $\text{BPP}$ algorithm $p \geq 2/3$. Call an $a \in \{0, 1\}^N$ bad if the above algorithm sees the correct answer for less than $p - \epsilon$ fraction of $z$’s. If the set of all bad $a$’s were to have size more than $2^k$, the $(N, k)$-source $X$ corresponding to drawing uniformly at random from the bad $a$’s would satisfy

$$\Pr[\text{Ext}(X, U_t) \in D] - \Pr[U_m \in D] > \epsilon,$$

which would contradict the assumption that $\text{Ext}$ is a $(k, \epsilon)$-extractor. We conclude that the probability that the above algorithm gets an incorrect answer from $A$ in $p - \epsilon$ fraction of the repeated runs is at most $2^k/2^N$.

16.7.4 Pseudorandom generators for spacebounded computation

Now we describe Nisan’s pseudo-random generators for space-bounded randomized computation, which allows randomized logspace computations to be run with $O(\log^2 n)$ random bits.

Throughout this section we represent logspace machines by their configuration graph, which has size $\text{poly}(n)$.

**Theorem 16.48 (Nisan)**

For every $d$ there is a $c > 0$ and a polynomial-time computable function $g : \{0, 1\}^{c \log^2 n} \rightarrow \{0, 1\}^{nd}$ such that for every space-bounded machine $M$ that has a configuration graph of size $\leq nd$ on inputs of size $n$:

$$\left| \Pr_{r \in \{0, 1\}^{nd}} [M(x, r) = 1] - \Pr_{z \in \{0, 1\}^{c \log^2 n}} [M(x, g(z)) = 1] \right| < \frac{1}{10}.$$  \hspace{1cm} (20)

We give a proof due to Impagliazzo, Nisan, and Wigderson [?] (with further improvements by Raz and Reingold [?]) that uses extractors. Nisan’s original paper did not explicitly use extractors —the definition of extractors came later and was influenced by results such as Nisan’s.

In fact, Nisan’s construction proves a result stronger than Theorem 16.48: there is a polynomial-time simulation of every algorithm in $\text{BPL}$ using $O(\log^2 n)$ space. (See Exercises.) Note that Savitch’s theorem (Theorem ??) also implies that $\text{BPL} \subseteq \text{SPACE}(\log^2 n)$, but the algorithm in Savitch’s proof takes $n^{\log n}$ time. Saks and Zhou [?] improved Nisan’s ideas to show that $\text{BPL} \subseteq \text{SPACE}(\log^{1.5} n)$, which leads many experts to conjecture that $\text{BPL} = \text{L}$ (i.e., randomness does not help logspace computations at all). (For partial progress, see Section ?? later.)
The main intuition behind Nisan’s construction—and also the conjecture $\mathsf{BPL} = \mathsf{L}$—is that the logspace machine has one-way access to the random string and only $O(\log n)$ bits of memory. So it can only “remember” $O(\log n)$ of the random bits it has seen. To exploit this we will use the following simple lemma, which shows how to recycle a random string about which only a little information is known. (Throughout this section, $\circ$ denotes concatenation of strings.)

**Lemma 16.49 (Recycling Lemma)**

Let $f : \{0, 1\}^n \to \{0, 1\}^s$ be any function and $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^t \to \{0, 1\}^m$ be a $(k, \epsilon/2)$-extractor, where $k = n - (s + 1) - \log \frac{1}{\epsilon ^{\ast}}$. When $X \in_R \{0, 1\}^n$, $W \in_R \{0, 1\}^m$, $z \in_R \{0, 1\}^t$, then

$$f(X) \circ W \approx_{\epsilon} f(X) \circ \text{Ext}(X, z).$$

**Remark 16.50**

When the lemma is used, $s \ll n$ and $n = m$. Thus $f(X)$, which has length $s$, contains only a small amount of information about $X$. The Lemma says that using an appropriate extractor (whose random seed can have length as small as $t = O(s + \log(1/\epsilon))$) if we use Lemma 16.43 we can get a new string $\text{Ext}(X, z)$ that looks essentially random, even to somebody who knows $f(X)$.

**Proof:** For $v \in \{0, 1\}^s$ we denote by $X_v$ the random variable that is uniformly distributed over the set $f^{-1}(v)$. Then we can express $\| (f(X) \circ W - f(X) \circ \text{Ext}(X, z)) \|$ as

$$\frac{1}{2} \sum_{v, w} \left| \Pr[f(X) = v \land W = w] - \Pr[f(X) = v \land \text{Ext}(X, z) = w] \right|$$

$$= \sum_v \Pr[f(X) = v] \cdot \| W - \text{Ext}(X_v, z) \|$$

(21)

Let $V = \{ v : \Pr[f(X) = v] \geq \epsilon / 2^{s+1} \}$. If $v \in V$, then we can view $X_v$ as a $(n, k)$-source, where $k \geq n - (s + 1) - \log \frac{1}{\epsilon ^{\ast}}$. Thus by definition of an extractor, $\text{Ext}(X_v, r) \approx_{\epsilon/2} W$ and hence the contributions from $v \in V$ sum to at most $\epsilon/2$. The contributions from $v \not\in V$ are upperbounded by $\sum_{v \not\in V} \Pr[f(X) = v] \leq 2^s \times \frac{\epsilon}{2^{s+1}} = \epsilon/2$. The lemma follows. $\blacksquare$

Now we describe how the Recycling Lemma is useful in Nisan’s construction. Let $M$ be a logspace machine. Fix an input of size $n$ and view the graph of all configurations of $M$ on this input as a *leveled branching program*. For some $d \geq 1$, $M$ has $\leq n^d$ configurations and runs in time $L \leq n^d$. Assume without loss of generality—since unneeded random bits can always be ignored—that it uses 1 random bit at each step. Without loss of generality (by giving $M$ a separate worktape that maintains a time counter), we can assume that the configuration graph is leveled: it has $L$ levels, with level $i$ containing configurations obtainable at time $i$. The first level contains only the start node and the last level contains two nodes, “accept” and “reject”; every other level has $W = n^d$ nodes. Each level $i$ node has two outgoing edges to level $i + 1$ nodes and the machine’s computation at this node involves using the next bit in the random string to pick one of these two outgoing edges. We sometimes call $L$ the length of the configuration graph and $W$ the width.

For simplicity we first describe how to reduce the number of random bits by a factor 2. Think of the $L$ steps of the computation as divided in two halves, each consuming $L/2$ random bits. Suppose we use some random string $X$ of length $L/2$ to run the first half, and the machine is now...
at node v in the middle level. The only information known about X at this point is the index of v, which is a string of length $d \log n$. We may thus view the first half of the branching program as a (deterministic) function that maps $\{0, 1\}^{L/2}$ bits to $\{0, 1\}^{d \log n}$ bits. The Recycling Lemma allows us to use a random seed of length $O(\log n)$ to recycle X to get an almost-random string $\text{Ext}(X, z)$ of length $L/2$, which can be used in the second half of the computation. Thus we can run $L$ steps of computation using $L/2 + O(\log n)$ bits, a saving of almost a factor 2. Using a similar idea recursively, Nisan’s generator runs $L$ steps using $O(\log n \log L)$ random bits.

Now we formally define Nisan’s generator.

**Definition 16.51 (Nisan’s generator)**
For some $r > 0$ let $\text{Ext}_k : \{0, 1\}^{kr} \times \{0, 1\}^r \to \{0, 1\}^{2k}$ be an extractor function for each $k \geq 0$. For every integer $k \geq 0$ the associated Nisan generator $G_k : \{0, 1\}^{kr} \to \{0, 1\}^{2k}$ is defined recursively as (where $|a| = (k - 1)r, |z| = r$)

$$G_k(a \circ z) = \begin{cases} z_1 & \text{(i.e., first bit of } z) \quad k = 1 \\ G_{k-1}(a \circ G_{k-1}(\text{Ext}_{k-1}(a, z)) & \quad k > 1 \end{cases}$$

Now we use this generator to prove Theorem 16.48. We only need to show that the probability that the machine goes from the start node to the “accept” node is similar for truly random strings and pseudorandom strings. However, we will prove a stronger statement involving intermediate steps as well.

If nodes u is a node in the configuration graph, and s is a string of length $2^k$, then we denote by $f_{u, 2^k}(s)$ the node that the machine reaches when started in u and its random string is s. Thus if s comes from some distribution $D$, we can define a distribution $f_{u, 2^k}(D)$ on nodes that are $2^k$ levels further from u.

**Theorem 16.52**
Let $r = O(\log n)$ be such that for each $k \leq d \log n$, $\text{Ext}_k : \{0, 1\}^{kr} \times \{0, 1\}^r \to \{0, 1\}^{kr}$ is a $(kr - 2d \log n, \epsilon)$-extractor. For every machine of the type described in the previous paragraphs, and every node u in its configuration graph:

$$\| f_{u, 2^k}(U_{2^k}) - f_{u, 2^k}(G_k(U_{kr})) \| \leq 3^k \epsilon, \quad (22)$$

where $U_l$ denotes the uniform distribution on $\{0, 1\}^l$.

**Remark 16.53**
To prove Theorem 16.48 let $u = u_0$, the start configuration, and $2^k = L$, the length of the entire computation. Choose $3^k \epsilon < 1/10$ (say), which means $\log 1/\epsilon = O(\log L) = O(\log n)$. Using the extractor of Section 16.6.4 as $\text{Ext}_k$, we can let $r = O(\log n)$ and so the seed length $kr = O(r \log L) = O(\log^2 n)$. 
We use the Recycling Lemma. Let \( \epsilon_k \) denote the maximum value of the left hand side of (22) over all machines. The lemma is proved if we can show inductively that \( \epsilon_k \leq 2\epsilon_{k-1} + 2\epsilon \). The case \( k = 1 \) is trivial. At the inductive step, we need to upperbound the distance between two distributions \( f_{u,2^k}(D_1), f_{u,2^k}(D_4) \), for which we introduce two distributions \( D_2, D_3 \) and use triangle inequality:

\[
\| f_{u,2^k}(D_1) - f_{u,2^k}(D_4) \| \leq \sum_{i=1}^{3} \| f_{u,2^k}(D_i) - f_{u,2^k}(D_{i+1}) \| .
\]  

(23)

The distributions will be:

- \( D_1 = U_{2^k} \)
- \( D_4 = G_k(U_{kr}) \)
- \( D_2 = U_{2^{k-1}} \circ G_{k-1}(U_{(k-1)r}) \)
- \( D_3 = G_{k-1}(U_{(k-1)r}) \circ G_{k-1}(U'_{(k-1)r}) \)  

\( (U, U') \) are identical but independent.

We bound the summands in (23) one by one.

\textbf{Claim 1:} \( \| f_{u,2^k}(D_1) - f_{u,2^k}(D_2) \| \leq \epsilon_{k-1} \).

Denote \( \Pr[f_{u,2^k-1}(U_{2^{k-1}}) = w] \) by \( p_{u,w} \) and \( \Pr[f_{u,2^k-1}(G_{k-1}(U_{(k-1)r})) = w] \) by \( q_{u,w} \). According to the inductive assumption,

\[
\frac{1}{2} \sum_w |p_{u,w} - q_{u,w}| = \| f_{u,2^k-1}(U_{2^{k-1}}) - f_{u,2^k-1}(G_{k-1}(U_{(k-1)r})) \| \leq \epsilon_{k-1}.
\]

Since \( D_1 = U_{2^k} \) may be viewed as two independent copies of \( U_{2^{k-1}} \) we have

\[
\| f_{u,2^k}(D_1) - f_{u,2^k}(D_2) \| = \sum_v \left| \frac{1}{2} \sum_w p_{uw}p_{wv} - \sum_w p_{uw}q_{wv} \right|
\]

where \( w, v \) denote nodes \( 2^{k-1} \) and \( 2^k \) levels respectively from \( u \)

\[
= \sum_w p_{uw} \frac{1}{2} \sum_v |p_{wv} - q_{wv}|
\]

\[
\leq \epsilon_{k-1} \quad \text{(using inductive hypothesis and } \sum_w p_{uw} = 1) \]

\textbf{Claim 2:} \( \| f_{u,2^k}(D_2) - f_{u,2^k}(D_3) \| \leq \epsilon_{k-1} \).

The proof is similar to the previous case.

\textbf{Claim 3:} \( \| f_{u,2^k}(D_3) - f_{u,2^k}(D_4) \| \leq 2\epsilon \).

We use the Recycling Lemma. Let \( g_u : \{0,1\}^{(k-1)r} \rightarrow [1, W] \) be defined as \( g_u(a) = f_{u,2^k-1}(G_{k-1}(a)). \)  

(To put it in words, apply the Nisan generator to the seed \( a \) and use the result as a random string for the machine, using \( u \) as the start node. Output the node you reach after \( 2^{k-1} \) steps.) Let \( X, Y \in U_{(k-1)r} \) and \( z \in U_r \). According to the Recycling Lemma,

\[
g_u(X) \circ Y \approx \epsilon g_u(X) \circ \Ext_{k-1}(X, z),
\]
16.7. APPLICATIONS OF EXTRACTORS

and then part 3 of Lemma 16.39 implies that the equivalence continues to hold if we apply a (deterministic) function to the second string on both sides. Thus

\[ g_u(X) \circ g_w(Y) \approx g_u(X) \circ g_w(\text{Ext}_{k-1}(X, z)) \]

for all nodes \( w \) that are \( 2^{k-1} \) levels after \( u \). The left distribution corresponds to \( f_{u, 2^k}(D_3) \) (by which we mean that \( \Pr[f_{u, 2^k}(D_3) = v] = \sum_w \Pr[g_u(X) = w \land g_w(Y) = v] \)) and the right one to \( f_{u, 2^k}(D_4) \) and the proof is completed. ■

Chapter notes and history

The results of this section have not been presented in chronological order and some important intermediate results have been omitted. Yao [?] first pointed out that cryptographic pseudorandom generators can be used to derandomize \( \text{BPP} \). A short paper of Sipser [?] initiated the study of “hardness versus randomness,” and pointed out the usefulness of a certain family of highly expanding graphs that are now called dispersers (they are reminiscent of extractors). This research area received its name as well as a thorough and brilliant development in a paper of Nisan and Wigderson [?]. Missing discussion of followup works to NW94.

Weak random sources were first considered in the 1950s by von Neumann [?]. The second volume of Knuth’s seminal work studies real-life pseudorandom generators and their limitations. The study of weak random sources as defined here started with Blum [?]. Progressively weaker models were then defined, culminating in the “correct” definition of an \((N, k)\) source in Zuckerman [?]. Zuckerman also observed that this definition generalizes all models that had been studied to date. (See [?] for an account of various models considered by previous researchers.) He also gave the first simulation of probabilistic algorithms with such sources assuming \( k = \Omega(N) \). A succession of papers has improved this result; for some references, see the paper of Lu, Reingold, Vadhan, and Wigderson [?], the current champion in this area (though very likely dethroned by the time this book appears).

The earliest work on extractors —in the guise of leftover hash lemma of Impagliazzo, Levin, and Luby [?] mentioned in Section 16.6.3— took place in context of cryptography, specifically, cryptographically secure pseudorandom generators. Nisan [?] then showed that hashing could be used to define provably good pseudorandom generators for logspace.

The notion of an extractor was first formalized by Nisan and Zuckerman [?]. Trevisan [?] pointed out that any “black-box” construction of a pseudorandom generator gives an extractor, and in particular used the Nisan-Wigderson generator to construct extractors as described in the chapter. His methodology has been sharpened in many other papers (e.g., see [?]).

Our discussion of derandomization has omitted many important papers that successively improved Nisan-Wigderson and culminated in the result of Impagliazzo and Wigderson [?] that either \( \text{NEXP} = \text{BPP} \) (randomness is truly powerful!) or \( \text{BPP} \) has an subexponential “simulation.” Such results raised hopes that we were getting close to at least a partial derandomization of \( \text{BPP} \), but these hopes were dashed by the Impagliazzo-Kabanets [?] result of Section 16.3.

\(^7\)The “simulation” is in quotes because it could fail on some instances, but finding such instances itself requires exponential computational power, which nature presumably does not have.
Trevisan’s insight about using pseudorandom generators to construct extractors has been greatly extended. It is now understood that three combinatorial objects studied in three different fields are very similar: pseudorandom generators (cryptography and derandomization), extractors (weak random sources) and list-decodable error-correcting codes (coding theory and information theory). Constructions of any one of these objects often gives constructions of the other two. For a survey, see Vadhan’s lecture notes [?].

Still a lot missing

Expanders were well-studied for a variety of reasons in the 1970s but their application to pseudorandomness was first described by Ajtai, Komlos, and Szemeredi [?]. Then Cohen-Wigderson [?] and Impagliazzo-Zuckerman (1989) showed how to use them to “recycle” random bits as described in Section 7.B.3. The upcoming book by Hoory, Linial and Wigderson (draft available from their web pages) provides an excellent introduction to expander graphs and their applications.

The explicit construction of expanders is due to Reingold, Vadhan and Wigderson [?], although we chose to present it using the replacement product as opposed to the closely related zig-zag product used there. The deterministic logspace algorithm for undirected connectivity is due to Reingold [?].

Exercises

§1 Verify Corollary 16.6.

§2 Show that there exists a number \( \epsilon > 0 \) and a function \( G : \{0,1\}^* \to \{0,1\}^* \) that satisfies all of the conditions of a \( 2^{\epsilon n} \)-pseudorandom generator per Definition ??, save for the computational efficiency condition.

§3 Show by a counting argument (i.e., probabilistic method) that for every large enough \( n \) there is a function \( f : \{0,1\}^n \to \{0,1\} \), such that \( H_{avg}(f) \geq 2^{n/10} \).

§4 Prove that if there exists \( f \in E \) and \( \epsilon > 0 \) such that \( H_{avg}(f)(n) \geq 2^{\epsilon n} \) for every \( n \in \mathbb{N} \), then \( MA = NP \).

§5 We define an oracle Boolean circuit to be a Boolean circuit that have special gates with unbounded fanin that are marked ORACLE. For a Boolean circuit \( C \) and language \( O \subseteq \{0,1\}^* \), we define by \( C^O(x) \) the output of \( C \) on \( x \), where the operation of the oracle gates when fed input \( q \) is to output 1 iff \( q \in O \).

(a) Prove that if every \( f \in E \) can be computed by a polynomial-size circuits with oracle to SAT, then the polynomial hierarchy collapses.

(b) For a function \( f : \{0,1\}^* \to \{0,1\} \) and \( O \subseteq \{0,1\}^* \), define \( H_{avg}^O(f) \) to be the function that maps every \( n \in \mathbb{N} \) to the largest \( S \) such that \( \Pr_{x \in \{0,1\}^n}[C^O(x) = f(x)] \leq 1/2 + 1/S \).

§6 Prove Lemma 16.39.
16.7. APPLICATIONS OF EXTRACTORS

§7 Prove that for every function \( \text{Ext} : \{0,1\}^n \rightarrow \{0,1\}^m \) and there exists an \((n, n-1)\)-source \( X \) and a bit \( b \in \{0,1\} \) such that \( \Pr[\text{Ext}(X)_1 = b] = 1 \) (where \( \text{Ext}(X)_1 \) denotes the first bit of \( \text{Ext}(X) \)). Prove that this implies that \( \delta(\text{Ext}(X), U_m) \geq 1/2 \).

§8 Show that there is a constant \( c > 0 \) such that if an algorithm runs in time \( T \) and requires \( m \) random bits, and \( m > k + c \log T \), then it is not possible in general to simulate it in a blackbox fashion using an \((N, k)\) source and \( O(\log n) \) truly random bits.

\[ \text{Hint: For each source show that there is a randomized algorithm—} \]

§9 A flat \((N, k)\) source is a \((N, k)\) source where for every \( x \in \{0,1\}^N \) \( p_x \) is either 0 or exactly \( 2^{-k} \).

Show that a source \( X \) is an \((N, k)\)-source iff it is a distribution on flat sources. In other words, there is a set of flat \((N, k)\)-sources \( X_1, X_2, \ldots \) and a distribution \( \mathcal{D} \) on them such that drawing a sample of \( X \) corresponds to picking one of the \( X_i \)'s according to \( \mathcal{D} \), and then drawing a sample from \( X_i \).

\[ \text{Hint: For each source show that there is a randomized algorithm—} \]

§10 Use Nisan’s generator to give an algorithm that produces universal traversal sequences for \( n \)-node graphs (see Definition ??) in \( n^{O(\log n)} \)-time and \( O(\log^2 n) \) space.

§11 Suppose boolean function \( f \) is \((S, \epsilon)\)-hard and let \( D \) be the distribution on \( m \)-bit strings defined by picking inputs \( x_1, x_2, \ldots, x_m \) uniformly at random and outputting \( f(x_1)f(x_2) \cdots f(x_m) \).

Show that the statistical distance between \( D \) and the uniform distribution is at most \( \epsilon m \).

§12 Prove Lemma 16.42.

§13 (Klivans and van Melkebeek 1999) Suppose the conclusion of Lemma ?? is true. Then show that \( \text{MA} \subseteq \text{i.o.}-[\text{NTIME}(2^n)/n] \).

(Slightly harder) Show that if \( \text{NEXP} \neq \text{EXP} \) then \( \text{AM} \subseteq \text{i.o.}-[\text{NTIME}(2^n)/n] \).

§14 Let \( A \) be an \( n \times n \) matrix with eigenvectors \( u^1, \ldots, u^n \) and corresponding values \( \lambda_1, \ldots, \lambda_n \). Let \( B \) be an \( m \times m \) matrix with eigenvectors \( v^1, \ldots, v^m \) and corresponding values \( \alpha_1, \ldots, \alpha_m \).

Prove that the matrix \( A \otimes B \) has eigenvectors \( u^i \otimes v^j \) and corresponding values \( \lambda_i \cdot \alpha_j \).

§15 Prove that for every two graphs \( G, G' \), \( \lambda(G \otimes G') \leq \lambda(G) + \lambda(G') \) without using the fact that every symmetric matrix is diagonalizable.

\[ \text{Hint: Use Lemma 7.40.} \]
§16 Let $G$ be an $n$-vertex $D$-degree graph with $\rho$ combinatorial edge expansion for some $\rho > 0$. (That is, for every a subset $S$ of $G$’s vertices of size at most $n/2$, the number of edges between $S$ and its complement is at least $\rho d|S|$.) Let $G'$ be a $D$-vertex $d$-degree graph with $\rho'$ combinatorial edge expansion for some $\rho' > 0$. Prove that $G \circledast G'$ has at least $\rho^2 \rho' / 1000$ edge expansion.

**Hint:** Every subset of $G \circledast G'$ can be thought of as a subset of $G$ or $G'$, the latter use the expansion of $G'$, while for the former use the expansion of $G$, which is larger.

**Acknowledgements**

We thank Luca Trevisan for cowriting an early draft of this chapter. Thanks also to Valentine Kabanets, Omer Reingold, and Iannis Tourlakis for their help and comments.
